AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS

EDITORIAL COMMUNICATIONS

Editorial communications, including manuscripts submitted for publication or inquiries concerning the JOURNAL, should be addressed to Varden Fuller, Department of Agricultural Economics, University of California, Davis, California 95616. (See inside back cover for Guide for Submitting Manuscripts.)

Communications concerning books for review and books submitted for announcement in the JOURNAL should be addressed to Allen B. Paul, Economic Research Service, United States Department of Agriculture, Washington, D.C. 20250.

SUBSCRIPTIONS

· Members of the American Agricultural Economics Association receive the JOURNAL as part of their membership.
· Yearly subscriptions, $25. Price this issue $5.
· Subscriptions, orders for individual copies of the JOURNAL and changes of address of subscribers should be addressed to John C. Redman, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.

· The AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS is issued five times a year, in February, May, August, November, and December. Prior to 1968, this JOURNAL was the JOURNAL OF FARM ECONOMICS.
· Published by the American Agricultural Economics Association.
· Printed by the George Banta Company, Inc., Menasha, Wisconsin, U.S.A.
· Second-class postage paid at Lexington, Kentucky, and additional mailing offices.

Flow-of-Funds Social Accounts for the Farm Sector*

John B. Penson, Jr., David A. Lins, and George D. Irwin

Flow-of-funds accounts and component sources-and-uses-of-funds statements relate changes in balance sheet accounts to income statements, describing movement from one balance sheet to the next. While the Federal Reserve System compiles a *farm business sector* sources-and-uses-of-funds statement consistent with and part of the national flow-of-funds accounts, the statement is not definitionally and conceptually consistent with published farm income and balance sheet accounts. An alternative *farm sector* sources-and-uses-of-funds statement is proposed that contains these features, and its potential applications and extensions are delineated.

Policy and predictive questions facing agricultural economists today increasingly involve a financial dimension. These questions require analysts to relate farm income streams and other sources of funds to changes in balance sheet items. Often comparisons are needed on a sector or subsector basis as well as for national aggregates. We suggest that few agricultural economists are familiar with social accounts that treat financial questions involving distinct sectors—the flow-of-funds social accounts.

The basic purposes of this article are: (1) to bring attention of agricultural economists to the concepts of flow-of-funds accounting, including the sector sources-and-uses-of-funds statement, with the hope of stimulating professional interest; (2) to present a sources-and-uses-of-funds statement for the farm sector corresponding to the sector definitions employed in the USDA farm income and balance sheet accounts; (3) to illustrate briefly how the flow-of-funds matrix and its component sources-and-uses-of-funds statement provide additional useful insights into the functioning of the farm economy; and (4) to touch on various ways that expansion of the accounts could more meaningfully describe relevant relationships in an increasingly integrated economy.

The Rationale of Flow-of-Funds Accounts

One of the major purposes of a national accounting system is to help piece together a variety of statistical information as an aid in analyzing structural and operational aspects of the economy. As one of the more recently developed systems, "the flow-of-funds accounts . . . . are as indispensible for understanding developments and interrelationships in financial markets as the national income accounts are for understanding trends in production and real output" [13, p. 4].

Concepts of the accounts

Copeland conducted much of the pioneering work in the field, constructing what were then known as money flows [4]. The Federal Reserve System (FRB) began in 1948 to define and construct a national flow-of-funds (FOF) matrix that could be updated on a regular basis. These efforts resulted in an initial set of accounts encompassing the 1939–53 period. They were updated quarterly and are now based on technique revisions made in 1959 and 1962 [2, 3]. One basic generalization from Copeland's approach was the shift from measuring money flows alone to measuring flows involving all financial transactions. Money remains the unit of account, but the change in holdings of money is only one component of the financial transactions that are measured.

The central idea of constructing flow-of-funds accounts can be described mechanistically in three simple steps: divide the economy into sectors; develop a sources-and-uses-of-funds (SAUF) statement of all financial transactions for each sector; place them side by side to get a FOF matrix.[1] The difficulties come when attempting to implement the procedures in a way that is both theoretically and empirically meaningful. This involves defining unique sectors (transactors) and sources and uses (transactions). These definitions may be conditioned by the availability of data with which to estimate flows.

* Helpful comments on an earlier draft from C. B. Baker of the University of Illinois, John E. Lee, Jr., and Allen Smith of the Farm Production Economics Division, ERS, USDA, and Stanley Sigel of the Federal Reserve System are greatly appreciated. The views and conclusions are the author's and are not to be attributed to the U.S. Department of Agriculture.

John B. Penson, Jr., David A. Lins, and George D. Irwin *are agricultural economists with the Farm Production Economics Division of the Economic Research Service, USDA. Penson and Lins are stationed at the University of Illinois; Irwin, at Purdue University.*

[1] Financial transactions may be identified by the fact that an asset owned by one transactor exists as a liability on the balance sheet of another party. Taken together, financial assets and liabilities offset each other for the economy as a whole.

Analysis of the accounts

An FOF matrix can be viewed as an ex post record of the flows through which the supply and demand for financial assets are equilibrated. The accounts aid in tracing through the process by which purchases of real assets are financed, as well as in studying the volume and content of purely financial activities. Duesenberry [4, p. 180] points out, however, that FOF accounts do not in themselves reveal the implications behind the financial interactions but rather record the results of these interactions. To gain an understanding of the financial process, one would have to examine more than one FOF matrix with the knowledge of what "shocked" the economy between the two periods in question. Thus, in addition to their descriptive function, the accounts can serve as data for econometric models designed to measure and test relationships. Tobin [4, p. 190] suggests that an explanation of the basic behavior behind FOF analysis requires examining the flows, considered as adjustments of individual balance sheets, toward a desired allocation of asset and debt holdings between successive time periods.

The accounts for a single sector (SAUF statement) may be examined or even estimated separately. The sector SAUF statement (and hence the overall FOF matrix) is an accounting system that combines features of a given sector's income statement with balance sheet changes. Our analysis will be concerned with (1) describing a currently available SAUF statement for the *farm business* sector, (2) constructing an alternative *farm* sector SAUF statement to allow direct comparisons with the *Balance Sheet of the Farming Sector* (*BSFS*) and *Farm Income Situation* (*FIS*), and (3) suggesting ways in which the SAUF statement approach can be used to improve our data for understanding the farm economy.

The Farm Business Sector SAUF Statement

FRB flow-of-funds accounts have been developed on a farm business sector basis, whereas most of us think in terms of an aggregate of firm-household units as a farm sector.[2] The former excludes personal and household activities of farm operators; the latter attempts to include most of them. The FRB uses income data supplied directly by the U.S. Commerce Department. The farm portion of these data is originated by the USDA with coverage modified by the Commerce Department to maintain consistency in their accounts. The FRB accepts the conventions inherent in the Commerce Department's farm business sector definition and adds assumptions of its own in deriving the farm business SAUF statement. Certain asset and debt data from the *BSFS* are also utilized.

On the basis that sources of funds (*SF*) must equal uses of funds (*UF*), categories of sources and uses are defined to isolate unique characteristics of the various flows. Certain conventions are followed in identifying particular flows as either source or use. If the flow is opposite to that implied by the accepted convention, it is entered as a negative value on the "conventional" side of the statement. Most of the figures reported are net change, though (as we suggest later) whenever data become available, gross flows are often much more revealing.

The FRB farm business sector SAUF statement may be summarized as follows:[3]

$$(1.1)\qquad UF = \sum_{i=1}^{N} (CE_i + \Delta FA_i)$$

where

$$\Delta FA = \sum_{i=1}^{N} (\Delta DDC_i + \Delta NLIC_i)$$

and

$$(1.2)\qquad SF = \sum_{i=1}^{N} (CC_i + RCE_i + NFY_i - PYW_i)$$

subject to

$$\sum_{i=1}^{N} (NFY_i - PYW_i) = 0.$$

[2] This difference in sectoral definition is also found in comparing national with farm balance sheet accounts and in comparing national with farm sector income accounts. For example, the USDA prepares farm income and balance sheet accounts for the farm sector, which includes aspects of operator households. The U.S. Department of Commerce aggregates the income data differently, splitting the totals to put part in a farm business sector and part in a consumer sector.

[3] Glossary of terms:
- CE = Capital expenditures plus net changes in inventories of current production.
- CC = Capital consumption.
- RCE = Retained earnings of farm corporations.
- ΔFA = Net change in financial assets.
- ΔCMI = Net change in credit market instruments.
- ΔTD = Net change in trade debt.
- PNI = Proprietor net investment.
- NFY = Net farm income.
- PYW = Proprietor income withdrawals.
- ΔDDC = Net change in demand deposits and currency.
- $\Delta NLIC$ = Net change in non-life insurance claims.
- N = Number of farm business enterprise units.

A crucial assumption made by the FRB is that all current net income is withdrawn from the farm business sector by noncorporate proprietors to the household sector. Proprietor net investment (PNI) is then calculated residually —whatever amount is necessary to equate sources and uses of funds. Given (1.1) and (1.2), one can solve the system for PNI:

$$PNI = \sum_{i=1}^{N} (CE_i + \Delta FA_i) - \sum_{i=1}^{N} (CC_i + RCE_i + \Delta CMI_i + \Delta TD_i) \tag{1.3}$$

One of the consequences of using these procedures will illustrate the kinds of interpretation problems they pose in relating to the USDA income and balance sheet series. The FRB farm business sector SAUF statement shows proprietors disinvesting in agriculture while the *BSFS* shows proprietors' equities rising from $178.6 billion in 1960 to $243.4 billion in 1969 [14]. This seeming contradiction arises for three reasons. First and most important for our immediate purposes, unrealized capital gains are a source of proprietors' equities in the *BSFS*, based on current market evaluation of real assets. The FRB farm business sector SAUF statement, on the other hand, records only actual transactions. Thus, capital gains are not recorded in the FRB account until they are realized. Changes in farm mortgage debt holdings are recorded, however, in the form of changes in outstanding credit market instruments. The question is: Should one assume a flow is created by unrealized capital appreciation? If so, should this form of investment be entered at full value or deflated by perhaps the rate of inflation? Second, the FRB farm business sector SAUF statement separates the household and business activities of the proprietor-family enterprise, assuming that all net farm income is withdrawn by the household and excluding farm family assets and income other than those attributable directly to farming. The *BSFS* does not make this distinction. It includes information on many of the financial assets of the "farm operator" residing on a "physical site," using this data to compute "proprietors' equities." Thus, one faces the problems of defining what the relative scope should be when constructing such accounts and of understanding clearly what is assumed when using preexisting sets of accounts. Third, the FRB farm business sector SAUF statement residually measures *proprietor* capital and financial investment in nonappreciable assets. The *BSFS* measures stocks of capital and financial investment in *all* real goods, from farm and nonfarm sources. Thus, one cannot com- compare these two existing accounts without making allowances for the differences in conceptual constructs.

Various definitional inconsistencies between the FRB farm business sector SAUF statement and the farm income and balance sheet series published by the USDA also impede inter-account comparisons. A semantics problem arises when two accounts contain the same figure but their nomenclature differs. For instance, "bank loans" in the FRB farm business sector SAUF statement includes the same items as "non-real estate debt of all reporting banks" in the *BSFS*. Discrepancies also occur when an item given the same name is defined differently in the two accounts. For example, the FRB account defines the "net increase in financial assets" to include net changes in demand deposits, currency, and non-life insurance company claims. The *BSFS*, on the other hand, defines the same item to include time deposits, demand deposits, currency, U.S. savings bonds, and investments in cooperatives, while excluding non-life insurance company claims. Which definition is appropriate depends, of course, on the scope, orientation, and use to be made of the estimates.

Alternative Farm Sector SAUF Statement

Past examination of social accounting techniques employed for the farm sector have shed considerable light on how the sector social accounts can be misinterpreted. The recent controversy over the "realized" farm income concept serves as one example [5, 7, 8, 11]. Irwin [9], in exposing three myths associated with the *Balance Sheet of Agriculture*,[4] suggested that reexamination of data series needs and orientation be a constant activity if we are to be able to measure the changing financial structure of the farm sector. Confronted by the potential usefulness[5] of FOF analysis but the lack of direct comparability between the FRB farm business

[4] The *Balance Sheet of Agriculture* has recently been renamed the *Balance Sheet of the Farming Sector* to clarify, among other things, the exclusion of related agribusiness firms from the account.

[5] In a later section we amplify on these uses. In order to do so, it is helpful to have estimates before us. We thus deviate for pedagogical reasons from the logical order in which the need is demonstrated before the work is done.

sector SAUF statement and existing farm sector social accounts, we have attempted to create a farm sector SAUF statement directly consistent with the USDA balance sheet and income series.

We are not suggesting changes in the FRB account since to do so would destroy its comparability with other sectors within the national FOF matrix. An alternative SAUF statement is needed that would capture the above points and be internally consistent with existing farm sector social accounts. Admittedly, growing involvement of farm operators in nonfarm activities (and vice versa) is creating interpretation problems. Our purpose here is not to make a case for either redefining or recognizing a change in the identity of the farm sector, but merely to adapt the SAUF statement to existing series. Ideally, one should be able to bridge from it to the FRB account whenever the analysis requires.

Again, given that sources of funds equal uses of funds for the sector, our suggested alternative SAUF statement for the *farm* sector is as follows:[6]

$$UF = \sum_{i=1}^{M}(NCE_i + \Delta I_i + IRE_i + \Delta FA_i) + PW \tag{2.1}$$

where

$$\Delta FA = \sum_{i=1}^{M}(\Delta DTC_i + \Delta GS_i + \Delta IC_i)$$

and

$$SF = \sum_{i=1}^{M}(CC_i + NFY_i + OFY_i + \Delta RED_i + \Delta NRED_i + CA_i) \tag{2.2}$$

Setting sources of funds equal to uses and solving this time for proprietor withdrawals (PW) residually:

$$PW = \sum_{i=1}^{M}(CC_i + NFY_i + OFY_i + \Delta RED_i + \Delta NRED_i + CA_i) - \sum_{i=1}^{M}(CE_i + \Delta I_i + IRE_i + \Delta FA_i) \tag{2.3}$$

Three changes are apparent in a comparison of equations (1.3) and (2.3). First, the alternative account measures withdrawals by the proprietor-family enterprise as a residual. Second, the alternative account treats nonfarm income as earnings, implying that the decision to work off the farm is a conscious decision about the use of farm resources, designed to enhance the overall earning power of the unit. Third, the alternative account includes capital appreciation as a source of funds. Capital appreciation is also a use of funds, being summed with capital expenditures on real estate assets to derive total investment in real estate assets (IRE).

The FRB account excludes almost all nonfarm activity, although conceptually sectors are supposed to be defined on an institutional rather than activity basis (see Ruggles [4, p. 93] and FRB [1, p. I. 34]. Though it certainly is an important issue, we do not wish to argue the merits of an activity-based account versus one that is a hybrid leaning toward the historic family farm institution. Our purpose is merely to attain comparability.

Conceptually, proprietor withdrawals may contain income, capital, and financial withdrawals by the proprietor-family enterprise unit. It is assumed that the net increase in financial assets are financial investments by the farm sector in other sectors of the economy. Proprietor capital investment (CI) in the farm sector is thus defined as net farm income and nonfarm income plus appreciation less proprietor withdrawals and financial investment in other sectors. Or stated another way:

$$CI = \sum_{i=1}^{M}(NFY_i + OFY_i + CA_i) - PW - \sum_{i=1}^{M}(\Delta FA_i) \tag{3.1}$$

If, for example, $PW + \Delta FA > NFY + OFY + CA_i$, proprietors have made a capital disinvestment

[6] Glossary of additional variable names:
PW = proprietor withdrawals.
OFY = nonfarm income of farm family.
IRE = total investment in real estate assets (includes appreciation gains).
ΔGS = net change in government security holdings.
ΔIC = net change in investment in cooperatives.
ΔRED = net change in real estate debt.
$\Delta NRED$ = net change in non-real estate debt.
ΔFA = net change in financial assets.
ΔI = net change in inventories of current production.
M = number of proprietor-family units.
ΔDTC = net change in demand deposits, time deposits, and currency.
NCE = non-real estate capital expenditure.
CA = capital gains in real assets.

in the farm sector. A capital disinvestment could be financed by increased debt as reflected in ΔRED and/or $\Delta NRED$, or alternatively, the result of capital depreciation of real assets.

Implicit in the above formulation is the assumption that all increases in *RED* and *NRED* represent investment by nonfarm sources in the farm sector. This assumption would be violated, for example, in the case of land sales financed by sellers, but only when a seller remains an active participant in the farm sector. The result is that our assumption leads to an overstatement of nonsector investment in the farm sector and a corresponding understatement of proprietor investment in the farm sector. The degree of overstatement of investment in the farm sector by nonfarm sources depends primarily upon the importance of active farmer-seller financing.

Empirical Application

Summaries of the FRB farm business sector SAUF statement and the alternative farm sector SAUF statement for 1967 are presented in Tables 1 and 2, respectively. The most important general result is found when comparing proprietor net investment with proprietor withdrawal. Proprietor net investment (*PNI*) of minus \$3.5 billion represents a net capital and financial disinvestment from the farm business sector. Proprietor withdrawals (*PW*) in Table 2 include income, capital, and financial withdrawals by the proprietor-family enterprise unit from the *farm* sector of \$28.1 billion. Employing formula (3.1), proprietor capital investment in the farm sector is \$6.1 billion, substantially higher than the amount reported in the FRB account.

Given the assumptions implicit in equation (3.1), one can calculate the total capital investment in the farm sector *from all sources* by summing proprietor capital investment and the net increase in *RED* and *NRED*. The calculation of total capital investment in the farm sector based on data in Table 2 need not correspond to the increase in physical assets in the *BSFS*. Inventory items in the *BSFS* are based on year-end prices, whereas inventories in the farm income statement are based on average prices for the year. One could make Table 2 consistent with the *BSFS* by replacing capital expenditures, capital consumption, and change in inventories with the net change in "non-real estate assets" figure in the *BSFS*.

One can reconcile the \$9.6 billion difference (\$6.1 − (−\$3.5)) between the proprietor capital

Table 1. Federal Reserve farm business sector sources-and-uses-of-funds statement, United States, 1967[a]

Transaction category	Uses of funds[b]	Sources of funds[b]
	billion dollars	
Current account		
Nonfinancial transactions		
1. Net farm income		14.4
2. Proprietor income withdrawal	14.4	—
3. Net saving of noncorporate businesses		0.0
4. Retained earnings of farm corporation		0.1
5. Capital consumption		5.7
6. Current surplus = gross saving		5.8

14. Net increase in liabilities		1.1
15. Credit market instruments		3.1
16. Mortgages		(1.8)
17. Bank notes		(0.7)
18. Other loans		(0.6)
19. Trade debt		1.5
20. Proprietor net investment		−3.5

[a] Adapted from unpublished data of the Federal Reserve System.
[b] Data used by the FRB are supplied directly by the U.S. Department of Commerce. Several items differ from USDA figures because of adjustment for sectoral definition.

and financial investment in the FRB farm business sector SAUF statement and proprietor capital investment in our alternative farm sector SAUF statement as follows:

(1) \$9.9 billion difference due to the inclusion of appreciation in real estate assets in the alternative account;

(2) \$0.3 billion difference due to the different interpretations of the net increase in financial assets;

(3) \$0.1 billion difference in the measurement of the net increase in debt; and

(4) \$0.1 billion difference due to the inclusion of retained corporate earnings (*RCE*) in the FRB account, an item that is consolidated with net farm income in the alternative account.

For 1967, items (3) and (4) cancel each other, leaving items (1) and (2) to account for the \$9.6 difference between the two statements.

Table 2. Alternative farm sector sources-and-uses-of-funds statement, United States, 1967.[a]

	billion dollars	
Sources of funds		
1. Net farm income[b]	14.6

14. Proprietor withdrawals	28.1	
Total uses of funds	45.6	

[a] Items 1, 2, 3, 7, and 8 were taken directly from the 1968 *FIS*. Items 4, 5, 6, 9, 10, 11, 12, and 13 were taken directly from the 1968 *BSA*.
[b] Includes income from corporate and noncorporate enterprise units.
[c] Not classified as a capital expenditure because the farm business and the household unit were treated as one.

Potentials and Directions

These estimates represent a first attempt to translate the flow-of-funds concept to a sector basis comparable to USDA farm income and balance sheet accounting coverage. Our alternative account is highly consolidated, both because it is a first attempt and because of our desire to use *BSFS* and *FIS* published data. Still, we believe the statement in these more familiar terms gives a basis for understanding the disinvestment conclusion implicit in the FRB farm business sector SAUF statement.

But this demonstration merely scratches the surface of potential applications and extensions. Let us briefly suggest three. The simplest would be more grossing of entries within limits of presently collected financial data on agriculture. To illustrate, one could show the amount of new mortgage money committed as a source of funds and the amount of principal payments as a use of funds, instead of just the $2.2 billion net increase. This more detailed information adds interpretive content and can be provided, given any predetermined set of account transactions. Second, one could disaggregate the alternative account by expanding the number of transaction categories. Mortgage and contract paper on land held by nonactive farmers who sell out would likely be interpreted as a different kind of investment from that held by financial intermediaries. The decision on what kinds of transactions should be considered structurally unique requires us to refine our theories. Third, a more general and more data-demanding form of disaggregation would be to expand the number of transactors or sectors. This could be carried on in at least two fruitful ways. One would be to disaggregate the present farm sector defined in our alternative account into several sectors. Depending upon what was judged most important, operators could be separated from landlords, one economic class of farm from others, those producing one type of product from others, those in one geographical location from others, those with one legal form of organization from others, and so forth. Again, it is largely a matter of theorizing which groups may have unique financial flow characteristics that are meaningful in explaining economic behavior. The other method of disaggregation among transactors would be to add sectors for farm-related businesses as a device for measuring the extent and kinds of financial interdependence being created by vertical integration, etc. Perhaps the rest of the economy could be entered as a separate sector for analysis. Costs and sources of data place severe limits on how far such reporting can be carried.

If the accounts are to be put to analytic uses in order to derive economic parameter estimates, and not just as a descriptive mechanism, further analysis is needed. One possibility is the simulation of a system of estimators for the components of the farm sector SAUF statement. This could be used as a framework to measure and test relationships of the various components.[7]

Summary

Flow-of-funds analysis as a social accounting tool is a necessity when measuring the changing financial structure of the farm sector. Much of its value lies in disaggregating flows of funds

[7] By adopting certain conventions for exogenous variables, one could solve the proposed system of equations, say on a recursive basis, over time. Our preliminary efforts in this area indicate that a simultaneous solution of the equations would be required.

from various institutional and noninstitutional sources of funds to various classes of users, i.e., economic classes of farms, operators, landlords, etc. This would aid in analyzing both the efficiency of the sources of funds in meeting demand and the relative benefits to groups of users who are supplied. This framework could provide the basis for new policy determination and for welfare comparisons under present programs not otherwise possible.

The purpose of FOF analysis in a national economic accounting system is to relate changes in balance sheets with income accounts. For our purposes, the role of FOF analysis is to relate changes in current accounts as given in the *Farm Income Situation* to changes in the *Balance Sheet of the Farming Sector*; to describe *how* we moved from one year's balance sheet to the next. Thus, it is important that the sector SAUF statement be definitionally and conceptually consistent with the *FIS* and *BSFS*. The scope and orientation of the FRB farm business sector SAUF statement is designed as part of their national FOF matrix. Thus, its basis is not internally homogeneous with the other farm sector social accounts.

Agriculture is blessed in certain respects with a multitude of statistical data sources. In terms of social accounting, continual examination of these sources as they relate to what it is we really are to measure is required. A coordinated effort to make the various accounts as consistent as possible is necessary if we are to prevent either their misuse or their nonuse.

Needed Redirections in Economic Analysis for Agricultural Development Policy*

Peter Dorner

Economic literature identifies development with average rates of increase in real output per capita. Little research has focused on interrelations between productivity increases and other indicators of development such as the reduction of mass poverty, unemployment, and inequality. Such omissions may be a function of the way agricultural economics developed in the United States. Here a positive correlation between increased production, employment, and income-earning opportunities was assumed inherent in the family farm system and the relative labor-scarce conditions. Problems emerging in recent years throw considerable doubt on the appropriateness of these assumptions.

I

Within the past several decades, especially the one just ended, agricultural economists have become increasingly concerned with agricultural *development* policies. I underline development since this is a new emphasis.[1] Agricultural economics and the related rural social sciences emerged as academic disciplines at about the turn of this century, after U.S. agriculture was far along the road to modernization. Initially, agricultural economists were concerned with problems of farm management and tenancy. Later, problems of marketing, credit, price and income protection, resource conservation, and aggregative characteristics of demand and supply became subfields of specialized interest and research. Since the discipline "grew up" after the basic economic, social, and political institutions of production and distribution were established, policy issues of concern to researchers were essentially those dealing with imperfections of the system—obstacles and barriers (to the free flow of information and resources) inhibiting the most efficient use and combination of *given* resources [24, pp. 725–729; 35, p. 83].

A look at the "growth of government in agriculture" [41, 1, 39] reveals a fairly close correspondence between policy issues in U.S. agriculture and the development of specialized areas of research.[2] The shape of agricultural economics as a discipline reflects the range of issues that arise in agricultural policy. Organized systems of thought are the result of man's efforts to cope with experienced difficulties. The configuration of such a system of thought will be different if establishment of basic institutions is a key issue, in contrast to the system of thought that emerges from inquiry into policy issues that arise *within* an established and accepted institutional framework [14, p. 4].

At the time of United States' independence, economics was just emerging as a recognizable, separate branch of moral philosophy. A major policy issue in the late 18th and early 19th century was the nature of economic organization to establish in agriculture. The resulting system of family farms was rationalized more in terms of political theory (a major reaction to European feudalism) than economic theory [16].

The system of economic, social, and political organization was firmly established by the time problems of agricultural policy attracted the attention of professional economists. Had our earlier policies fostered a feudal hierarchy or communal ownership of land instead of fee simple ownership and family farms; had our social organization developed around the extended family or the tribe instead of the nuclear family living in relative isolation on its farmstead; had our political system been one of centralized control and management of the economy with all transactions involving land, labor, capital, and commodities regulated by

* I gratefully acknowledge the many helpful comments on earlier drafts by colleagues at the Land Tenure Center, especially Marion Brown, William Thiesenhusen, Don Kanel, Herman Felstehausen, Elsa Chaney, Kenna Jarvis, and John Bielefeldt. Some of the basic formulations developed in this paper originated in my many discussions over the years with Ken Parsons, Carl Bögholt, and Ray Penn. I acknowledge my indebtedness to them.

[1] Development is here viewed in the broad sense of expanding opportunities and the human capacities needed to exploit them, along with a general reduction of mass poverty, unemployment, and inequality [36, 31].

Peter Dorner *is professor of agricultural economics and director of the Land Tenure Center at the University of Wisconsin.*

[2] Note also current policy issues (poverty, resource and environmental management, population, urban congestion, agricultural development, etc.) and the corresponding growing interest and research specialization (including new institutes and professional journals) in all of these areas.

central political authority instead of the local automony and free private enterprise of individuals in their economic activities; much of our theory of the firm, of markets, of pricing, and of equilibrium would be irrelevant. In fact, we most likely would not have them. *They could be developed and perfected only within a particular political and institutional context.* They provide no analytical insight into a system whose institutions are different.[3]

Thus, there is little reason to believe that the concepts and hypotheses derived from our theories are entirely relevant to all of our country's currently recognized problems; they are even less to relevant to problems facing the poor, agricultural countries. The need, it would seem, is to understand institutional systems and the nature of public policy issues.

On some problems our theories and professional economic analyses are serving reasonably well in the United States and in other industrialized countries. The relevant questions are being asked and the data needed for analyses are being generated. But the categories in our census and other statistical series are not accidental.[4] They too are products of the policy issues and the theoretical formulations developed through the interaction of problems and ideas.

On other important policy questions, however, present theories provide little insight even on U.S. issues: environmental quality, poverty, race relations, a more acceptable distribution of economic and political power, congested cities, rural development, automation, and basic changes in the structure of resource ownership. Present theories do not seem to encompass these issues; they do not help us to formulate the right questions; hence, appropriate data are not available, and fundamental policy questions tend to fall outside the boundaries of traditional academic disciplines.[5]

II

A basic question is whether economics, or any other social science, has anything significant to say on matters of development policy. More fundamentally, are the social sciences capable of generating guidelines for public policy that are in some sense "better" than those formulated by other means and criteria? Or are the value questions of public policy subject only to political compromise or the dictates of dogma, coercion, and personal tastes?

This depends, it seems, on one's view of the role of theory, how it is developed, and the manner in which it is tested. If one assumes that economic theory develops in some pure form independent of policy issues existing within a specific institutional matrix, it follows that theory can have an "independent career" and be set apart in a separate domain.[6] This view may not be too harmful with respect to those aspects referred to by Kuhn as "normal science" or the "mop-up work" growing out of established theory.[7]

[3] N. Georgescu-Roegen has observed, "As soon as we realize that for economic theory an economic system is characterized exclusively by institutional traits, it becomes obvious that neither Marxist nor Standard theory is valid as a whole for the analysis of a non-capitalist economy, i.e., of the economy of a society in which part or all of the capitalist institutions are absent. A proposition of either theory may eventually be valid for a non-capitalist economy, but its validity must be established *de novo* in each case . . . . Even the analytical concepts developed by these theories cannot be used indiscriminately in the description of other economies. Among the few that are of general applicability there is the concept of a production function together with all its derived notions. But this is due to the purely physical nature of the concept. Most economic concepts, on the contrary, are hard to transplant . . . " [13, pp. 147–148].

[4] Seers has noted that " . . . lack of data on poverty, unemployment and inequality reflects the priorities of statistical offices rather than the difficulties of data collection. The conceptual problems of these measures do not seem to be more formidable than those of the national income. We have just grown accustomed to ignoring [them]" [36, p. 3].

[5] "Nowhere," says John Gardner, "can the operation of vested interests be more clearly seen than in the functioning of university departments . . . [the department] assesses the significance of intellectual questions by the extent to which they can be answered without going outside the the sacred territory" [12, p. 98].

[6] "To accept the distinction between 'pure' and 'applied' economics as generally valid and fundamental is not only to accept the view that 'theory' in its pure form can have an independent career but that it can be validated in some way other than by 'application' . . . The crux of the issue is simply this: that the only alternative which we have to the validation of inquiry by problem solving is a reliance either upon self evidence of fact or principle as the foundations of knowledge—or upon revelation. Both of the latter alternatives are incompatible with a genuinely scientific viewpoint" [30, pp. 664 and 674]. (See also [6].)

[7] "Mopping-up operations are what engage most scientists throughout their careers. They constitute what I am here calling normal science. Closely examined, whether historically or in the contemporary laboratory, that enterprise seems to attempt to force nature into the preformed and relatively inflexible box that the paradigm supplies. No part of the aim of normal science is to call forth new sets of phenomena; indeed those that will not fit the box are often not seen at all. Nor do scientists normally aim to invent new theories, and they are often intolerant of those invented by others.* Instead, normal scientific research is directed to the articulation of those phenomena and theories that the paradigm already supplies" [22, p. 24].

* Here Kuhn cites Bernard Barber, "Resistance by Scientists to Scientific Discovery," *Science* 134:596–602, 1961.

Another position, taken in this paper, is that as major changes occur in society the existing body of theory (developed through the study and eventual resolution of major policy issues) becomes inadequate and fails to comprehend the new policy issues that confront society. The major breakthroughs and theoretical syntheses in economics have come about from attempts to deal with major policy crises. Smith, Ricardo, Marx, and Keynes were all deeply immersed in the policy issues of their time, and their theoretical advances resulted from their inquiry into the possible resolution of questions central to economic policy.[8] Advances in theory have always been constructed on the basis of detailed and specific research into the very issues that could not be forced "into the preformed and relatively inflexible" boxes available from existing theory [22, p. 24].

Emphasizing the need for research on policy issues does not mean that the goals of policy are set by politicians, bureaucrats, or pressure groups and that the role of research is merely to seek the most efficient means of arriving at such predetermined goals. Rather, it means that the investigator must be concerned with both ends and means. "Since development is far from being achieved at present, the need is not, as is generally assumed, to accelerate economic growth—which could even be dangerous—but to change the nature of the development process" [36, p. 3].

This view holds certain dangers. For example, it raises the question of objectivity in research.[9] This is perhaps why many social scientists deny that they are working on policy questions and maintain that—as scientists—their only concern is establishing value-neutral relationships. This latter function is of great social significance, and most social scientists will be engaged only in such studies. Indeed, new theoretical breakthroughs are impossible without them [22]. But without direct attention to relationships not prescribed by present theories, some of the most pressing public policy questions are ignored.

It may be helpful at this point to note a fundamental difference between the physical and the social sciences. Both physical and social scientists can carry on much of their normal science under laboratory conditions, but social scientists will always conduct some of their research within the context of human society. When a crisis in policy emerges, when accepted theories fail to offer insights into phenomena readily observed, when these anomalies become so obvious that they can no longer be ignored, a new theory cannot be validated except as it is tested in practice. In physical science this can still frequently be done under laboratory conditions; but in economics it requires new directions in policy. Its measured consequences must then serve as the experimental test. The Keynesian reformulation of the 1930's is perhaps the best and most recent example in the field of economics. Today, many economists are indeed engaged in the normal science that is not directly concerned with ends or values. But this is made possible by the new Keynesian paradigm which has once again (for the industrialized, capitalist countries) relegated many evaluative or "normative" issues to the level of assumption, removing them for the time being from the immediate field of inquiry. This makes possible the common practice of reading prescriptions for public policy directly from the refined Keynesian models (a practice which Keynes himself did not recommend).[10] But such prescriptions could not command the respect they do if the new theoretical constructions had not been tested—in the only meaningful terms possible—through their practical influence in shaping public policy and resulting in measured and anticipated consequences.

In the United States we have begun to accept as a measure of progress the number of people lifted from the misfortune of being poor. There is a growing recognition that development prob-

[8] "One of the results of any survey of the development of economic doctrines is to show that in large measure the important departures of economic theory have been intellectual responses to changing current problems" [25, p. 13].

[9] The problem-solving approach to inquiry " . . . easily and naturally frays out into a mere servicing of practical judgments. In fact, it requires strenuous intellectual effort to avoid this very outcome. Under such circumstances we gradually drift into an acceptance of the 'problems' as formulated by our constituency. The next step is simply that of making 'investigators' the mere tools of various interests . . . Yet the issue must be faced. The argument seems inexorable, that there is no other alternative in genuinely scientific inquiry to having both the roots of inquiry and the final tests of validity in practical problem solving" [30, pp. 675–676].

[10] "The object of our analysis is, not to provide a machine, or method of blind manipulation, which will furnish an infallible answer, but to provide ourselves with an organised and orderly method of thinking out particular problems; and, after we have reached a provisional conclusion by isolating the complicating factors one by one, we then have to go back on ourselves and allow, as well as we can, for the probable interactions of the factors amongst themselves. This is the nature of economic thinking" [21, p. 297].

lems are not confined to some far-off "less-developed country," and people are beginning to realize that development is more than capital, investment, and markets. It is a complicated process of institutional change, redistribution of political power, human development, and concerted, deliberate public policy efforts for redistributing the gains and losses inherent in economic growth [7, p. 291].

Despite such recognition, these issues are still often treated as "fringe problems," outside the mainstream of economic policy. And development economics, so far as I can determine, does not incorporate these issues into its analysis. As a result, the relevancy of development economics to development is being questioned [36, 4]. In viewing the core economic theory requirements at major Ph.D.-granting universities and the content of preliminary examinations, one would hardly suspect that such problems exist or that theory has any bearing on research related thereto.[11] While development questions in the United States are becoming more critical, they are at the heart of public policy issues in nonindustrialized countries. Yet U.S. universities are presuming to educate and confer Ph.D. degrees on candidates from these countries.[12]

There is, it would appear, a crisis situation developing in economics (and perhaps in the social sciences generally) in the sense defined by Kuhn—"Crisis and the Emergence of Scientific Theories" [22, pp. 66–76]. Unless some key development issues, presently ignored, are directly addressed in research, this crisis may challenge the very legitimacy of economics. As Boulding reminds us,

> The teaching of every profession produces a certain amount of what Veblen called "trained incapacity" and we should certainly look with a critical eye at economics to see if we are not doing this. If the training of the economist leads to his neglecting certain important aspects of the world about him, once he is in a position to give advice and to have his advice taken, disasters might easily ensue. . . When one is giving advice, therefore, about a system that involves the total society, it is extremely dangerous to be overtrained in a certain abstract element of the total process. If we run into enough of this we may find indeed a widespread reaction against economics and a withdrawal of legitimacy from it. It is my own view frankly, at this point, that we must move toward a more integrated and perhaps even a rearranged social science, that the existing departmental and disciplinary lines often mask real problems. . . [2, pp. 306–307].

III

Given the rapid population growth in most of the developing countries, the large proportion in agriculture, and the continuing growth of absolute numbers dependent upon agriculture [9], it is surprising to see how little analytical attention has been given to the need for creating employment and improved income-earning opportunities in rural areas. There is a vague hope that programs designed to increase production will result in agricultural development irrespective of the short-run employment and distributional consequences of such programs. However, experience over the past decade indicates that the questions of increased agricultural production and a more equitable distribution of the fruits of that production must be viewed as parts of the same process. Policies designed to cope with one of these to the exclusion of the other have not succeeded.

These two aspects of development (increased production and a more equitable distribution) are sometimes viewed as being totally independent [3]. The first is seen as the key to development while the second is considered a peripheral problem of welfare or social justice. Some even assume that economists have the analytical tools that permit them to make policy recommendations for increased efficiency in production, but that the problem of a more equitable distribution is a political or cultural matter [17].

In most of the nonindustrialized countries a majority of the people depend on the land for employment; jobs in manufacturing are growing much less rapidly than manufacturing output; and the number of people dependent on farming for a livelihood is increasing. To achieve the benefits that may accrue from what Owen has called "farm-financed social welfare" requires that opportunities—even subsistence opportunities—be provided [27, p. 61; 28].

Policies that emphasize modernization and

---

[11] "Workshop on Core Economics" sponsored by the Agricultural Development Council, October 10–11, 1967, held at ADC offices in New York.

[12] "If a student's formal course training is limited to two years of graduate study and he expects to work on development problems, he is, I'm afraid, in danger of finding that he has acquired a lot of mental luggage of dubious utility while he has not been expected to think very deeply on questions basic to an effective attack on the problems of development. It is not really an answer to say that you are giving him his analytical tools and that his thinking can come later. If he has not been made aware of the basic issues in his university training, he may well pass through life unaware of their very existence" [4, p. 20].

increased production from the commercial farm sector without explicit attention to the creation of employment opportunities will yield increased output of certain farm commodities and growing labor productivity for a part of the farm labor force. But they tend to widen the income disparities and throw the burden of adjustment on the disadvantaged who join the ranks of the landless, become migrant seasonal workers, continue to crowd into existing small farm areas, move out to rapidly shrinking frontiers, or join the underemployed in the cities. There is no evidence that the increased volume of commodities moving through commercial channels as a result of increased production creates sufficient jobs for workers displaced by modernization or for the continuing new additions to the rural labor force.

Poverty (the massive poverty among the majority of people in the less-developed countries) is not only or primarily a welfare and humanitarian problem. It is a problem that has direct and important implications for increased productivity. Supply *does not* create its own demand under conditions of a highly skewed income distribution. To focus primarily on production widens the income gap between rich and poor. It is impossible in many circumstances of development to separate the issues of production and distribution, since distributional measures may be the key to achieving increases in production. And the trickle-down theory of distribution has never worked, especially under conditions of concentrated economic and political power.[13]

Why are policies not formulated to accommodate both of these requirements—increased production and increased employment with a more equitable distribution? The distributional questions, of course, raise many tough issues. Accordingly, and regretfully, policy recommendations of professional analysts using highly sophisticated models usually ignore employment and distributional aspects. Recommendations are too often based on private or project decision-making criteria rather than those appropriate to the interests of the entire nation. Some redirections in economic analysis are required. Three concepts in such a redirection (and examples of assumptions that frequently preclude their explicit inclusion in analyses) are highlighted in the following sections.

1. *Creation of secure opportunities on the land.* The "war on hunger" position tends to assume that if there are hungry people, food should be produced by the cheapest, most efficient means possible. Yet frequently, and especially when viewed from the private interest of an individual firm, this course of action includes displacing people with machines. And professional analysts, viewing the problem with decision-making criteria appropriate to the private firm while ignoring the possible lack of correspondence between private and social costs and benefits, can reach conclusions such as the following: "One reason for the high cost [of corn in Guatemala] is the amount of hand labor required. Hence, my desire to try out the corn picker" [29, p. 716]. However, this may not be a solution at all once the need for employment creation is taken into account. Even if means could be found to tax away or otherwise confiscate the increased production ". . . a nation cannot put most of itself on the dole, even if money and food are available for distribution" [26, p. 224].

Land must be viewed as a vehicle for human development as well as a resource for food production. As Raup has put it, "Wherever there is surplus agricultural labor and shortage of working capital, the task of the tenure system is to put people to work" [33, p. 274].

It has become an article of faith, at least among many professionals from the industrialized countries, that mechanization (mechanical technology and automation generally) always creates as many jobs as it destroys, sometimes more. According to this faith, there may indeed be some short-run problems of labor displacement and some structural unemployment. But given time, the new technology creates demand for labor in many areas of the economy through its various linkages, and eventually employment will rise to a higher level.

This assumption may be justified in a highly industrialized nation. But does the same assumption apply to a country that does not produce its own technology? In the United States, for example, the mechanical cotton picker displaced workers by the tens of thousands [5]. Many of the workers displaced (though certainly not all) and especially the sons of these workers did find employment among the vast

[13] *The Economist* makes the following comments on FAO's "Indicative World Plan": "As long as incomes are so unevenly distributed within the developing countries themselves, and so little inroad is made with their traumatic unemployment problems, the people who are starving will not have the money to buy the food, even if it is there. This is where the planners of Asia, Africa and South America would like FAO guidance, but so far they only get alarming figures and some general advice" [15, p. 75].

complex of industries interrelated with the production, sale, and servicing of cotton pickers—steel, rubber, oil, machinery manufacture, transport, farm implement sales and service, etc. But what about Nicaragua, which imports cotton pickers from the United States? Most of the vast complex of industries linked with the cotton picker does not exist in Nicaragua; it remains in the manufacturing country.[14]

The entrepreneur of a large farm enterprise may find the importation of labor-displacing machines highly profitable due to a variety of circumstances, many of them related to government policies: overvalued exchange rates, subsidized credit, rising minimum wages and fringe benefits, etc. Reasoning from analogy, U.S. and European experience of farm enlargement and mechanization is sometimes cited to support this type of development. But such an analogy is inappropriate for the widely different situation with respect to factor proportions and *real* factor costs in nonindustrial societies (in contrast to existing factor prices which are often controlled and distorted by some of the above policies) [11].

The cotton picker case illustrates the general principle involved; it does not argue against all modern, imported technology. Much depends on what the machines will be used for. In an agriculture with an overabundant and growing labor supply; it is unlikely that one can make a logical case for importation of labor-saving machinery if the problem is viewed from the standpoint of national policy rather than profit maximization of the firm [19]. If the agricultural sector is to make its most effective contribution to economic development, it must not only improve labor productivity for a select group but must also expand employment opportunities [20, 40].

Mechanical power and equipment might sometimes be justified in terms of increased yields due to better tillage or timeliness of operations. But there is sufficient experience of countries where such needed machine services were provided to an agriculture otherwise based on labor-intensive production practices.

On the basis of his model of rural outmigration and urban unemployment, Todaro concludes:

> Perhaps the most significant policy implication emerging from the model is the great difficulty of substantially reducing the size of the urban traditional sector without a concentrated effort at making rural life more attractive [40, p. 147].

But how is rural life to be made more attractive? Presumably public investments in rural education and health services would help; and funds used to accommodate rural migrants in the cities might be diverted to rural areas. Yet such services cannot be extended rapidly because of both capital and professional manpower shortages. Higher minimum wages for farm workers could be counterproductive so long as investment decisions in the farm sector are made by private entrepreneurs. A higher minimum wage might lead to a shift to labor-extensive enterprises or to an acceleration of machine substitution for labor. Even with low wages there is a strong incentive on large farms to mechanize and simplify labor supervision. It is almost impossible to find farms of, say, 1,000 hectares in rice or cotton that are planted, tended, and harvested mainly by hand labor. These farms either mechanize or operate with a sharecropper system. To get at the crux of the matter, "making rural life more attractive" in most cases means providing the farm family with ***a secure opportunity on the land.*** Land tenure arrangements and size of holdings must be included as variables in the analysis. But the basic assumptions underlying production and distribution theories take these as "givens."[15]

---

[14] The problem is compounded if, as Singer has pointed out, the investments and the production processes are actually controlled by foreigners. "The main secondary multiplier effects, which the textbooks tell us to expect from investment, took place not where the investment was physically or geographically located but (to the extent that the results of these investments returned directly home) they took place where the investments came from. I would suggest that if the proper economic test of investment is the multiplier effect in the form of cumulative additions to income, employment, capital, technical knowledge, and growth of external economies, then a good deal of the investment in underdeveloped countries which we used to consider as 'foreign' should in fact be considered as domestic investment on the part of the industrialized countries" [37, p. 475].

[15] "Distribution theory today concerns itself, in essence, with tracing out the effects of various policies in distributing economic fruits among persons who own or otherwise command control over resources . . . In current theory, distribution of ownership or other control of resources among people is 'given' . . . In terms of the dynamics of economic development, however; the real problem of distribution is: 'How does ownership or other control over resources come to be distributed in the manner it is?' . . . The question is not, for example, whether a landlord and a tenant each receives the appropriate return for the resources he controls; but rather, is it appropriate, from the standpoint of the economic development of the country in question, for the landlord and the tenant to have these particular proportions of the nation's resources under his control" [24, pp. 729–730].

2. *Development of human abilities and capacities.* Another reason why the employment issue gets little attention is that in the less-developed countries, the most abundant potential resource usually is labor. I say *potential* because training and work experience are needed to transform raw labor power into the manpower resource (with skills, experience, and discipline) required for development. An abundance of people does not necessarily rule out labor shortages in selected occupations. The scarcest resource generally is capital. Given the abundance of people, there has been a tendency to ignore the need for investment in and development of the labor potential. Instead of viewing land as a vehicle for employing people and for developing the skills and experience required of the rural labor force, land has been viewed primarily as a resource to be efficiently combined with scarce capital so as to maximize agricultural output.

T. W. Schultz has written a good deal on the issue of investment in human capital [34], but he places primary emphasis on formal schooling. I do not deny this need, but formal schooling is not the only and not always the most significant dimension of education. Furthermore, many poor countries have not yet been able to supply even elementary schooling for large numbers of their people. Under these circumstances, economic activity should be designed to produce educational effects. Productive work can offer experience and discipline as valid as that gained in the classroom. It is different, to be sure, and neither kind of education is alone sufficient. Work experience can be directed and enriched by learning obtainable only from school situations; schoolroom education can be enhanced by work experience.

The manner in which increased production is achieved, and the number of people who participate and reap some benefits from the experience, may be as important as the production increase itself. One gets a different perspective regarding the role of land if (in addition to its accepted function in the production of farm products) it is viewed as a vehicle both for creating economic opportunities and upgrading the human skills and capacities required for their exploitation [8, p. 12].

Man is a resource to be used (along with land and capital) as well as the user of resources. An individual plays a dual role—he is both the user and the used, the interested and the object of interest, the exploiter and the exploited.

In a society where economic and political power are widely shared, there is a continuous attempt to modify institutional structures and norms in order to keep this process of "using others" mutually beneficial. Procedures are designed so that individuals and groups, in pursuing their private interests, are not injuring (preferably, are furthering) the interests of other individuals and groups. When mutuality in the process breaks down and conflicts intensify, zones of discretionary behavior of the individuals and groups involved must be redefined in order to reestablish mutuality in the processes of associated living.

The common formulation in resource allocation-efficiency models is to view man as labor power—as the object of use. This view, far from being value-neutral, accepts the status quo power positions and ownership patterns of land and capital. In fact it places the weight of authority of "scientific analysis" in the camp of present owners. Under conditions of vast and increasing inequality, policy prescriptions based on such efficiency models are consistent with the poor man's view of the world: "Them that has—gets".

3. *Inclusion of income distribution as a variable in analyses.* Economic literature tends to deemphasize the income distribution consequences of the development process. Since land tenure arrangements are most directly associated with the creation of and access to income-earning opportunities and their distribution, these arrangements receive only passing mention in the economic literature on agricultural development policies.

If the task of development is conceptualized to include income distribution as an endogenous variable, some of the economists' most powerful ideas and tools lose some of their analytical leverage. For example, marginal analysis and the accompanying planning, programming, and budgeting tools implicitly assume certain nonchanging structural parameters. Yet once an elaborate and somewhat arbitrary measurement emerges, as from benefit-cost analysis, a strong faith is placed in it. The unstated assumptions remain unstated and are frequently ignored. The higher the benefit-cost ratio, the "better" the project.

However, the results of these calculations are directly conditioned by the pattern of income distribution.[16] Investments in the increased

---

[16] "... Cost-benefit analysis as generally understood is only a technique for taking decisions within a framework which has to be decided upon in advance and which in-

production of chickens and beans rather than airlines and television sets might give a good benefit-cost ratio if the pattern of income distribution were changed. Poor people, lacking the money votes, cannot register their needs or desires through the market mechanism. But change the income distribution and you change the structure of demand, thus changing the benefit-cost ratios of various projects and in turn altering investment priorities.[17]

Assumptions like those described in these examples allow certain strategic developmental questions to fall between the analytical slats: productive employment for the growing rural labor force; creation of opportunities for the development of human abilities and capacities; and ownership distribution of land and other resources. An agricultural economist, using a farm management approach, may ignore the displacement of workers or their need to find viable opportunities on the land. He is concerned with profit maximization from the resources available to the firm. Even an agricultural economist dealing with farm policy for the agricultural sector could ignore these questions on the assumption (well founded or not) that industrial and other nonagricultural activities are available for the absorption of excess rural labor. Nor does a macroeconomic approach assure that these strategic questions will be addressed in the analysis. While Keynes may have shown a deliberate disregard for the supply side of investments (and focused only on their demand-creating consequences) [23], post-Keynesian development economists seem to have overemphasized the supply consequences.

There is indeed an implicit assumption that somewhere policies are being implemented to maintain full employment and that when a laborer moves from one job to another it always results in increased productivity. But these are unwarranted assumptions in most cases of less-developed countries. Indeed, these assumptions point to some of the critical problems of development.[18]

IV

What conclusions are to be drawn from the arguments set forth in this paper? First, we need additional criteria by which to assess development. This means inclusion of presently less measurable and quantifiable variables than the commonly accepted ones in use today. Second, both ends and means must be incorporated as variables in the analysis rather than accepting certain ends implicit in standard economic theories. Finally, distributional questions must be given higher priority on the research agenda.

Present theories may have much more relevance once we understand better the institutional context of specific country development problems and the "special case" out of which our own theories were constructed. If new theoretical extensions can accommodate the enlarged context, present theories may become more useful in guiding research in the very situations in which they are at present unsuccessful.[19]

New developments in theory are not simply willed into existence. The hypothesis suggested in this paper is that only as research concentrates on presently neglected policy issues within specific institutional contexts of individual countries can more adequate theories of agricultural development be constructed. It is

volves a wide range of considerations, many of them of a political or social character" [32, p. 685].

[17] Hirschman speaks of the centrality of side-effects in judging investment projects. "The quest for a unique ranking device probably accounts for the hostility of economists toward side-effect and secondary benefits. Yet this quest is clearly futile. How could it be expected that it is possible to rank development projects along a single scale by amalgamating all their varied dimensions into a single index when far simpler, everyday choices require the use of individual or collective judgment in the weighing of alternative objectives and in the trade-off between them? There is much to be said, it is true, for facilitating decision making by reducing the many aspects of a project to a few crucial characteristics, one of which would of course be the rate of return. It is one thing to permit, in this way, the decision maker to use informed judgment in making critical choices and trade-offs; it is quite another, however, for the technician to aim at dispensing with such judgment altogether" [18, pp. 162 and 179].

[18] ". . . [the] process of labor transfer is typically viewed analytically as a one-stage phenomenon, that is, a worker migrates from a low productivity rural job directly to a higher productivity urban industrial job. The question is rarely asked whether or not the typical unskilled rural migrant can indeed find higher-paying regular urban employment. The empirical fact of widespread and chronic urban unemployment and underemployment attests to the implausibility of such a simple view of the migration process" [40, p. 139].

[19] The theorist can be of help to the politician, the practitioner, ". . . if he refrains from trying to adapt uncritically models and measures designed in and for industrial countries, where priorities are different, but helps instead to develop policies, national and international, to mitigate the great social problems of the Third World . . . above all, the aim must be to change international attitudes so that it becomes impossible for the political leaders and social scientists of Europe and North America to continue overlooking, and aggravating, often inadvertently, the obscene inequalities that disfigure the world" [36, p. 6].

obviously asking a great deal of a man to be guided by present theories and preconceptions and yet to be continuously suspicious and to question them at every stage in his research. Nevertheless, this would seem to be the nature of the present challenge.

Optimal Sizes of Farms Under Varying Tenure Forms, Including Renting, Ownership, State, and Collective Structures*

EARL O. HEADY

Variants in tenure forms cause a range of optimal farm sizes in countries of various stages of economic development. Aside from capital restraints, however, modifications can be made in cost functions associated with each tenure form. The optimal use of inputs and farm size then is theoretically the same for individually operated farms. In the case of private, state, and cooperative farms, however, the same resolution is not possible in the short run. If the objective of the cooperative farm is maximum profit per member, this tenure form always has an optimal size smaller than a private or state farm.

FARMS over the world are operated under a wide variety of size and tenure conditions. The dominant tenure pattern in Eastern Europe is one of state farms and cooperatives (collectives) operated as very large units. Side by side with these units are individual plots (individual farms in Poland and Yugoslavia, with the acreage dominated by private farms over socialized units). Farms are smaller in North America and are operated under a combination of tenure conditions, including share renting, cash renting, and owner operation. Still, farms in North America generally are larger than in Western Europe, with a similar mixture of tenure conditions. Some large plantation units prevail in less developed countries of Africa, South America, and Asia, but very small units operated under either ownership or rental dominate.

The variants in tenure forms, stage of development, political objectives, and resource markets are expected to cause a range of farm sizes to be optimal in the several world regions. However, we may ask how the optimal size of farms should vary under these diverse conditions. Or we may ask whether the variation in farm sizes is consistent with this range of developmental and tenure conditions and the implied objective functions of societies. As an initial appraisal, it would appear that while farms are larger and more diversified in Eastern Europe, they should be smaller and less specialized than in Western Europe and North America.

We propose that farms in Western Europe and North America may be too small or that those of Eastern Europe may be too large. This proposition is made in terms of the potential nature of production functions, stages of economic development, and relative factor prices (or relative factor scarcities in countries where prices are not freely established in markets). It abstracts from the political, social, and institutional environment which may dominate and place (sometimes only subjectively but in other cases as a legislated extreme) upper restraints in land area per farm in some countries (usually individual or private units) and lower restraints (usually state and cooperative or collective units) in other countries. Aside from these nonmarket restraints, the technological and factor scarcity conditions in Eastern Europe should cause farms to be smaller, or optimally no larger, than those in North America. Of course, technology and factor prices would not dominate farm size if constant returns to scale prevailed. Farms of both large and small sizes could exist side by side on an equal economic basis. Or the pattern of one country could be large units while that of another country could be small units and both would be operated with equal efficiency. Under the potential of high mechanization, however, cost functions can decline over an extended volume of the farm firm's volume or land area. Hence, larger optimal farms may be posed in countries such as Western Europe and North America where development is at higher stages, capital has a lower real price relative to labor, and capital technologies are more consistent with factor markets.

Tenure and Size

We shall return to these conditions of development and resource supplies or markets which relate to farm size. However, tenure conditions also pose differences in optimal farm size. If cooperative (collective) farms were organized for maximum benefit of their members as typically implied (supposing consumer or societal welfare is maximized through use of

* Journal paper J-6503 of the Iowa Agricultural Experiment Station. Project No. 1328.

EARL O. HEADY *is Curtiss distinguished professor of economics and executive director of the Center for Agricultural and Economic Development at Iowa State University.*

factor prices or weights to attain efficient factor combinations and efficiency), their short-run size could well differ from that of private (individual) and state (public) farms. The conditions of tenure even under private land ownership and individual operation also should cause similar variations in optimal size. Hence, we turn first to an analysis of optimal farm size under conditions of share renting, cash renting, owner operation, cooperative farms, and state (public) units. The analysis in this study is only of optimality relative to an objective function for the individual farm. Resolution of the questions and problems posed can be attained finally only as empirical cost function research is completed over a range of countries to establish the nature of cost and scale economies under various conditions of factor markets and economic development. Also, in contrast to this analysis using the firm's objective function as the criterion, a parallel analysis is needed relating society optimality to factor markets, social institutions, the conditions of competition that prevail in agriculture, and other sectors of national economies and political objectives.

This analysis is in a theoretical context. Previously we developed certain theoretical concepts relating to the effect of tenure on farming efficiency, equitable divisions of income, and commodity supplies [4, pp. 587–588; 5, ch. 20 and 21; 6; 7, pp. 52–64]. Others have added to this theory over time [1, 2, 3, 9]. Helmberger and Hoos [8] and Phillips [10] have examined certain organization theory of cooperative enterprises. The current analysis differs, however, in relating specifically to farm size and various types of production functions which might prevail.

Size Under Share and Owner Operation

The optimal normative size of an individual farm operated under ownership is defined by the magnitudes of various resource inputs for the various commodities. While several commodities may be produced, our illustrations refer to a single commodity or enterprise in order to economize in space. A multicommodity farm involves exactly the same theory, extended accordingly. For all situations analyzed in this paper we assume the production function:

$$Y = f(X_1, \cdots, X_j, \cdots, X_n) \tag{1}$$

where Y is product output, the X_j are resource inputs, P_y is price per unit of output, and P_j is the price per unit of the jth input ($j=1, 2, \cdots, n$). This function refers to a particular production period and the X_j are resources or their services consumed in this period. (Consideration of multiperiod resources, uncertainty and discounted or compounded prices would extend the presentation but would not change the general conclusions. Hence, we leave them aside for reasons of space.) Ex post and normatively, the optimal farm size is defined by the magnitude of Y and the X_j which maximize the profit or objective function. The objective or profit function, π, in this case is

$$\pi = P_y Y - \sum_{j=1}^{n} P_j X_j \tag{2}$$

and the first-order conditions defining optimization of the objective function are

$$\begin{aligned} \frac{\partial Y}{\partial X_1} &= P_y^{-1} P_1 \\ &\vdots \\ \frac{\partial Y}{\partial X_j} &= P_y^{-1} P_j \\ &\vdots \\ \frac{\partial Y}{\partial X_n} &= P_y^{-1} P_n \end{aligned} \tag{3}$$

where the marginal productivity of the jth resource is equated to its real price (i.e., the price of the resource divided by the price of the product).[1] It is elementary knowledge that this state of optimization prevails, assuming pure competition or prices that serve as constant parameters for the individual farm and no X_j is fixed in supply, only under conditions where the marginal productivities of each resource is declining and

$$\sum_{j=1}^{n} \frac{\partial Y}{\partial X_j} \frac{X_j}{Y} < 1.0$$

(decreasing returns to scale) prevail; that under these conditions, the marginal value productivity of each resource is equal to its price, the marginal rate of substitution of each pair of resources is equal to their respective price ratio,

[1] As noted later, if the total budget for investment in inputs is limited to K_0, the marginal productivity of the jth input will be at the higher level $(1+\lambda_0)P_jP_y^{-1}$ and the farm size will be restrained to the level $K_0 - \sum_{j=1}^{n} P_jX_j = 0$ (i.e., the latter equation will be added to the set of partial derivatives and we must solve for the $n+1$ unknowns λ_0 and $X_1, \cdots, X_j, \cdots, X_n$).

and the specified volume of output is produced with the minimum cost mix of inputs.

Solving the equation system in (3), we can determine the values $X_1, \cdots X_j, \cdots X_n$ that specify optimal farm size in terms of a single resource category or as the weighted aggregation of inputs. Substituting these values in the production function, we also can specify the optimal size in terms of output volume. With the criterion of optimizing the objective function, this size not only is optimal for an individual farm operated under private resource ownership but also would be the optimal size for a state-owned farm which is provided weights (e.g., prices) for inputs and outputs and is instructed to maximize the objective function accordingly. Hence, under given conditions of climate and soils (i.e., the production function) and relative weights for inputs and outputs, the optimal size of a privately owned individual farm is exactly the same as for a publicly owned state farm if we suppose that each has the same economically defined objective function to optimize. The optimal size, thus specified, is not expected to extend over the vast range represented by state farms in the U.S.S.R. and the private farms in North America. Under these economic conditions and criteria, political and noneconomic facets left aside, either the state farms of the former may be too large or the individual farms of the latter may be too small. We return to this comparison after we complete the comparative analysis of optimal size for individual farms.

Turning now to a farm operated under share prices for resources, we have the tenant objective function:

$$\pi = rP_yY - \sum_{j=1}^{n} P_jX_j \tag{4}$$

where the tenant receives r proportion of the output ($r<1.0$ and the landlord receives $1\text{-}r$ proportion) but bears all of the input costs.[2] Substituting the production function (1) for Y in the tenant profit function (4) and deriving the marginal condition for profit maximization by the tenant, the marginal productivity of the the jth tenant resource is the magnitude in (5):

$$\frac{\partial Y}{\partial X} = r^{-1}P_y^{-1}P_x \tag{5}$$

It will be r^{-1} times greater ($r^{-1}>1.0$) than the marginal productivity of the same resource for the owner-operator. This greater productivity corresponds with a smaller input and therefore a smaller farm, as measured by resource magnitudes and output volume.

Under certain apparent conditions, the divergence in optimal size of individual farms under owner and share-rented conditions can be resolved as follows: If the tenant supplies s proportion of the inputs while the landlord supplies $1-s$ proportion, the tenant's objective function becomes (6). The corresponding landlord objective function is (7).

$$\pi_t = rP_yY - s\sum_{j=1}^{n} P_jX_j \tag{6}$$

$$\pi_1 = (1-r)P_yY - (1-s)\sum_{j=1}^{n} P_jX_j \tag{7}$$

The corresponding marginal condition for the jth resource under tenant and landlord profit maximization is that respectively in (8) and (9).

$$\frac{\partial Y}{\partial X_j} = sr^{-1}P_y^{-1}P_j \tag{8}$$

$$\frac{\partial Y}{\partial X_j} = \frac{(1-s)}{(1-r)}P_y^{-1}P_j \tag{9}$$

If r is not equal to s (i.e., if landlord and tenant do not share the cost of inputs in the same proportion as they share outputs), the optimal farm size, from the standpoint of objective function optimization, will differ in both cases from the optimal owner size as implied by the marginal conditions of (3). If $r<s$. the optimal tenant size will be smaller than for the owner while the optimal landlord size will be larger since then $(1-r)>(1-s)$.[3] If, however, we

[2] Under this formulation, if we suppose the tenant supplies all n resources, the tenant farm would be akin to a franchise for farming in which the operator supplies all resources and pays a share of the product as a price of the franchise or right to farm. We can look upon this as a "pure type" tenant farm in order to simplify the analysis. In reality, of course, the landlord furnishes the land and other resources; but the general logic is the same and we retain the "pure case" example for reasons of simplification. We have already analyzed resource efficiency and use in the short-run context of an owner furnishing a given land input and tenant supply of other resource inputs [5].

[3] The marginal productivity in (8) for tenant optimization will be larger than for the owner in (3). This conforms with lower inputs for the tenant and a smaller size or volume. Conversely, the optimal magnitude of the marginal product for the landlord in (9) is smaller than for either the tenant (8) and the owner (3) with a correspondingly larger farm posed.

make $r = s$, so that both tenant and landlord pay the same share of input costs and receive an identical share of the output, then $s\,r^{-1} = 1.0$ and $(1-s)(1-r)^{-1} = 1.0$ and the optimal magnitudes of the marginal products for tenant (8) and landlord (9) will be the same as for the owner-operator (3). Hence, solving the sets of marginal productivity equations for magnitudes of inputs each for the tenant, landlord, and owner-operator, farms of identical size will be specified.

However, these identical optimal farm sizes hold true only under certain capital supplies. Capital limitations must be of the same relative magnitude for all. In case $r = s$, but the tenant has an upper limit of K_t capital and the landlord has an upper limit of K_1 capital to invest in resources, their respective profit functions will be modified as in (10) and (11) where λ_t and λ_1 are conforming La Grange multipliers.

$$(10)\qquad \begin{aligned}\pi_t &= rP_yY - s\sum_{j=1}^{n} P_jX_j \\ &\quad + \lambda_t\left(K_t - s\sum_{j=1}^{n} P_jX_j\right)\end{aligned}$$

$$(11)\qquad \begin{aligned}\pi_1 &= (1-r)P_yY - (1-s)\sum_{j=1}^{n} P_jX_j \\ &\quad + \lambda_1\left[K_1 - (1-s)\sum_{j=1}^{n} P_jX_j\right]\end{aligned}$$

Now the conforming marginal conditions for optimization of the tenant and landlord objective functions are respectively (12) and (13).

$$(12)\qquad \frac{\partial Y}{\partial X_j} = (1+\lambda_t)sr^{-1}P_y^{-1}P_j$$

$$(13)\qquad \frac{\partial Y}{\partial X_j} = (1+\lambda_1)(1-s)(1-r)^{-1}P_y^{-1}P_j$$

The marginal productivities in (12) and (13) will be equal, and conforming optimal farm sizes will exist for tenant and landlord only if $\lambda_t = \lambda_1$. This condition will prevail only if $s^{-1}K_t = (1-s)^{-1}K_1$ since the set of partial derivatives in (3), denoting first-order conditions of profit maximization, has an added equation:

$$K_0 - \sum_{j=1}^{n} P_jX_j = 0$$

for an owner,

$$K_t - s\sum_{j=1}^{n} P_jX_j = 0$$

for the tenant, and

$$K_1 - (1-s)\sum_{j=1}^{n} P_jX_j = 0$$

for the landlord. Hence, K_0, K_t, and K_1 must be proportional to the shares of input quantities for owner, tenant, and landlord respectively if optimal farm sizes are to be equal in a "mixed tenure" of individual farms.

Short-Run Cost Functions for Cash, Share, and Owner Operation

Long-run optimal farm size from the standpoint of operator optimization and relatively equal capital supplies (degree of uncertainty, institutional arrangements, etc., being the same) should be the same for cash-rented and owner-operated farms, except for unique long-run variations (i.e., all factors variable and combined in optimal proportions). Hence, we need not distinguish between long-run optimal sizes for owners and cash tenants. Similarly, under competition and long-run market equilibrium, the cost function and theoretical equilibrium size of firms should be the same under cash rental and owner operation. However, some interesting differences do arise in short-run cost functions and theoretical size of farms for minimum average costs.

Suppose the short run is characterized by a fixed land input but other factors are allowed to vary. The situation might have prevailed in a country (e.g., the United States) where the number of acres is institutionalized (as once at 160 acres, a configuration that still relates to modal farm sizes available in the market). Such a short-run "fixed size" prevails fairly rigidly in some countries in providing a given area per farm (e.g., Poland, Yugoslavia, and some other countries). The farm firm can vary its volume of output (i.e., its size as expressed in production or investment in input categories other than the fixed resource). While the exact nature of average cost functions will depend on the production function, prices of factors and relative importance of the fixed and variable terms of the total cost function, let us suppose the short-run total cost function, T_0, in (14) for an owner operated farm where Y is output.

$$(14)\qquad T_0 = 100 - 10Y + 5Y^2$$

(We have "forced" the conventional U-shaped average cost function by supposing diminishing marginal productivity for other resources as they are increased on the fixed input or area

of land). Now, a cash tenant has the total cost function, T_c, in (15) where we suppose the fixed rent paid the land owner not only covers the previous fixed costs (where the landlord's and renter's fixed costs sum to 100) but also includes a return to the land owner's resources equal to half the fixed costs in (14).

$$T_c = 150 - 10Y + 5Y^2 \tag{15}$$

Further, suppose a share tenant who pays half of the production as rent to the landlord bears all the costs but has fixed costs (attached only to capital and not to real estate) equal to half of those for the owner-operator in (14). The share tenant's total cost function then is (16) where the variable cost component of the equation is twice (since he shares half the yield) that for the cash renter and owner-operator.

$$T_s = 50 - 20Y + 10Y^2 \tag{16}$$

The corresponding average cost functions for owner, cash tenant, and share tenant are respectively those indicated as AC_0, AC_c, and AC_s in Figure 1. The short-run farm size (the volume of output) which gives minimum average costs for the share tenant will come at a smaller output (2.24) than for the owner (4.47) under the above conditions. Similarly, the short-run size conforming to minimum average costs, $d(AC)/dy=0$, for the owner-operator (4.47) will be smaller than for the cash tenant (5.48).[4] The arrows at the bottom of the graph indicate output magnitudes that conform with minimum average costs in this short-run context.

The marginal cost function (as well as the average variable cost function) will be the same for owner and cash tenants but lower than for the share tenant. However, if the share tenant pays only half the cost of variable inputs (since $r=.5$ and then $r=s$), the marginal and average variable cost functions for the share tenant, cash tenant, and owner-operator will be the same. This change creates the average cost function denoted by AC_s' in Figure 1 whose minimum is at an output still different from that for cash or owner conditions. While the new minimum cost point is at a larger short-run size (3.16) than formerly (2.24) for the share tenant, it is still a smaller size (Y) than for the cash tenant and owner-operator. While, in terms of profit maximization, share-rented (with $r=s$), owner-operated and cash-rented farms would operate at the same output level (i.e., short-run optimal size would be identical since the marginal cost function then is $d(TC)/dY=10Y-10$ and the three tenant forms have the same short-run supply function), the functions still differ in short-run size (Y) to give minimum costs. Hence, if the short-run condition were converted institutionally into a "long-run" situation, as by placing an upper or given size or acreage through legislation as is done in some countries, the play of competitive market forces (through resource prices, including land and its rental rate, and commodity supplies and prices) would cause average revenue to equal average cost at different sizes of output (i.e., different long-run equilibrium sizes) under the three tenure conditions. A country of owned farms would have "medium-sized" equilibrium units; one of cash-rented farms would have "large-sized" units; and the country of share-rented farms (with

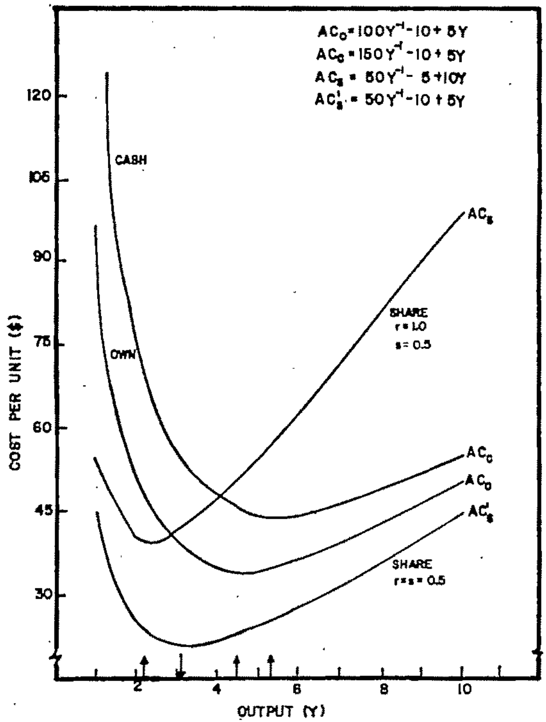

Figure 1. Cost functions and size for minima under different tenure forms

[4] While a specific algebraic form is used here, the condition is general for a short-run cost function where diminishing marginal productivity prevails for the variable factors and the fixed factor entails a higher outlay for the cash tenant and a lower outlay for the share tenant than for the owner-operator. The relative height of the functions and the slopes of the curves will, of course, vary with the relative magnitude of fixed and variable components of the cost function (i.e., on the nature of the production function and the prices of the different resources.)

tenants making the decision since, except in our illustration, the minimum point on the average cost function would be still different for the land owner) would have "small-sized" farms. In practice, of course, a wide range of these conditions prevail with custom, history, and institutions even restraining the acreage size. Hence, it is little wonder that farms vary so greatly in size and seem to survive equally in countries of mixed tenure systems.

Sizes Under State, Individual, and Cooperative or Group Structures

Another set of differing conditions under which farms of the world operate are those of individual, state, and cooperative (collective) organization. Farms of cooperative and state organization are typically large; those of individual organization are typically smaller. We now pose the question of which size is optimal under these three structures relative to certain implied objective functions. For purposes of simplicity, we assume the individual farm is owner-operated. Since the optimal size is identical for state and individual farms operated under the same production function, relative prices, and objective functions, we compare optimal sizes for individual and cooperative or group farms. We assume that the objective of the individual (state) farm is to maximize return or profit relative to the operating unit composed of all resources. For the group (cooperative or collective) farm composed of many members, we suppose the common and usually implied objective of maximizing return per member. We again use a "pure case" abstraction because space restrains discussion of all variants. The pure case assumes the same production functions and prices or weights. It also assumes that the cooperative members do not pay themselves a wage but organize the farm (select a size or investments) to maximize return per member.

For the sake of convenience and clarity, we initially assume a farm with the long-run production function in (17). Domar has discussed some conditions of equilibrium under classical, general conditions [2]. We provide our analysis relative to a range of forms in production functions which could prevail in the long run and short run. Since we first consider a long-run production function (all resources variable and increased in the same proportion), we can express the function in terms of one resource category. The nature of the production function is extremely important with respect to the organization of agriculture. If constant returns to scale prevail, there is no limit to optimal firm size, and the existence of extremely large-scale state and collective farms in Eastern Europe and the smaller family farms of Western Europe and North America are not inconsistent. Unfortunately, empirical scale studies are not widely available in any of these world regions (and less so in Eastern Europe) to indicate which conditions prevail. Without this knowledge, we initially assume the production function in (17) which has ranges of both increasing and decreasing returns to scale.

$$Y = aR + bR^2 - cR^3 \tag{17}$$

We use Y to denote output and R to denote resource input. (We suppose $R = r_1X_1, \cdots r_jX_j, \cdots r_{n-1}X_{n-1}$ where X_j is an individual resource, r_j is the proportion in which this resource is combined with R and all inputs are increased in these fixed, r_j, proportions). We may suppose R is labor and the X_j are the $n-1$ other resources. Hence, the function can be expressed as in (17) because all other resources are increased in the same proportion. We let X represent the aggregation ($X = r_1'X_1, \cdots r'_jX_j, \cdots r_{n-1}'X_{n-1}$) of other inputs held in fixed proportion. Hence, we have the two input prices P_r for labor and P_x as the aggregate price of other resources ($P_x = r_1'P_1, \cdots r_j'P_j, \cdots r_{n-1}^1P_{n-1}$). The private farm pays a price for all resources and has the objective or profit function:

$$\begin{aligned} \pi &= P_yY - (P_r + \alpha P_x)R \\ &= P_y(aR + bR^2 - cR^3) - (P_r + \alpha P_x)R \end{aligned} \tag{18}$$

where α is the ratio in which the aggregate resource X (nonlabor) is used with respect to R (labor). (A state farm will have the same objective function if it pays a price for all resources.) If we assume the objective for the group or cooperative farm is to maximize returns for its members (R or labor as the reflection of the member), its objective function is

$$\begin{aligned} \phi &= (P_yY - \alpha P_xR)R^{-1} \\ &= [P_y(aR + bR^2 - cR^3) - \alpha P_xR]R^{-1} \end{aligned} \tag{19}$$

In the cost term, we include only P_x or the price of the aggregate nonlabor resources (used in α proportion to labor) since the members do not pay the labor wage, P_r, to themselves but expect to get the return for their labor wage, P_r, along with other returns above fac-

tor costs from the proceeds of the farm firm. Since the objective of this "true cooperative" is to maximize return per member, we divide the difference of revenue and nonlabor costs by the amount of labor (i.e., multiply it by R^{-1} where R is the number of members or workers). Maximization of the objective (profit) for the individual farm is denoted by equation (20) where marginal profit (the derivative of equation (14) with respect to R) is equated to zero.

$$(20) \quad P_y(a + 2bR - 3cR^2) - P_r - \alpha P_x = 0$$

Maximization of the objective for the "pure cooperative" farm is denoted by equation (21) where the marginal labor return (the partial derivative of ϕ with respect to R in equation (19) also is equated to zero.

$$(21) \quad P_y(b - 2cR) = 0$$

Now, solving for the value of R in (20) and (21) to determine the optimal magnitude of labor input and farm size (since $R = \cdots r_jX_j \cdots$) for individual and cooperative farms, we obtain the values in (22) and (23) respectively.

$$(22) \quad R = .33bc^{-1} + [.33ac^{-1} - (P_r + \alpha P_x)(3cP_y)^{-1} + .109b^2c^{-2}]^{.5}$$

$$(23) \quad R = .5bc^{-1}$$

Several conditions are of interest. First, we note that the optimum size (the magnitude of R since $R = \cdots r_jX_j \cdots$) for the pure cooperative is not related to prices of output or nonlabor inputs. (The values of P_y and P_x do not occur in equation (23).) As indicated in (19), the magnitudes of P_y and P_x do affect the magnitude of returns per cooperative member, but they do not affect the optimum size or number of members (R) in (23). In other words, if P_y is higher (P_x is lower), cooperative members will have a higher income, but the same size is optimal regardless of prices. In contrast, the optimal volume or size for the individual farm (also a state farm under conditions specified previously) is a function of all prices. Optimally, it will be larger as output price increases and input prices decrease, or small under converse magnitudes of these prices. In the short run, the optimal individual farm would always be as large or larger (R will be greater) than the pure cooperative, the extent depending on P_y, P_r, and P_x.

Under classical long-run market equilibrium, however, the individual farm would have the same size as the optimal cooperative farm. The optimal pure cooperative farm size is that in equation (23), regardless of short-run or long-run conditions. Under long-run competitive market conditions, individual firms are expected to produce a volume denoting the minimum point on their long-run cost function. As is known for production function (17), this is the input level where the average productivity of resources is at a maximum. Hence, if we compute the average productivity function of R (divide equation (17) by R), and other resources (since $R = \cdots r_jX_j$) then take the derivative of Y with respect to R (and market equilibrium), the optimal size of the individual farm is identical with the universal size of the cooperative farm. But under no circumstances is the optimal size for the pure cooperative farm larger than for the individual farm.

Other Production Functions

We have provided results under a "general" production function. However, other production functions may prevail in agriculture, and we shall now examine two of these. Suppose we have a production function that (a) involves "set-up costs" in terms of resources (a minimum of resources is required before any output is attained and while k is negative, the meaningful value of the function begins at $Y=0$ and $R>0$) and (b) has diminishing marginal resource productivity as illustrated in (24).

$$24) \quad Y = -k + aR - bR^2$$

The corresponding objective functions, as characterized previously, are (25) and (26) respectively for the individual and pure cooperative farms.

$$(25) \quad \pi = P_y(-k + aR - bR^2) - (P_r + \alpha P_x)R$$

$$(26) \quad \phi = [P_y(-k + aR - bR^2) - \alpha P_xR]R^{-1}$$

Taking the first derivative of each equation, equating it to zero, and solving for the value of R, we have the optimal size of the individual farm in (27) and the optimal size (number of members) of the "pure cooperative" farm in (28).

$$(27) \quad R = .5ab^{-1} - .5b^{-1}P_y^{-1}(P_r + \alpha P_x)$$

$$(28) \quad R = (kb^{-1})^{.5}$$

Again, it is apparent that the optimal size (i.e., the value of R) for the pure cooperative farm is invariantly of this specified size regardless of price magnitudes. The optimal size of

the individual farm again is a function of both output and input prices and in all short-run cases where profit is greater than zero, it will have an optimal size larger than the pure cooperative.

We now examine the production function in (29) with marginal resource productivity constant at β. We suppose there is a natural endowment amounting to e (some "wild or natural product" is available regardless.)[5]

$$(29) \qquad Y = e + \beta R$$

The objective functions for private and pure cooperative farms are those respectively in (30) and (31).

$$(30) \qquad \pi = P_y(e + \beta R) - (P_r + \alpha P_x)R$$

$$(31) \qquad \phi = [P_y(e + \beta R) - \alpha P_x R]R^{-1}$$

The derivative of (30) is a constant, indicating that if the objective function of the private farm is greater than zero, $\beta > (P_r + \alpha P_x)P_y^{-1}$, there is no limit to its optimal size. However, for the pure cooperative objective function in (31) the value of ϕ declines positively for all values $R > 0$ (i.e., it is "meaningfully" maximum at $R = 0$). Hence, the pure cooperative would be as small as possible and if R represents members (labor) who must exist in integer values, the farm would be a "one-man" cooperative.

Other Implications

This paper establishes certain implications of optimization to firm size under alternative tenure forms. In a sense it provides hypotheses about reality which should now be empirically verified. The objective is not, however, to explain the political, social, market, and other forces that actually determine farm size in countries with contrasting social systems and at various stages of economic development. Farms that are both larger and smaller than the optimal specified under the criteria of this analysis may prevail entirely because of noneconomic objectives.

Later studies should deal with the economic and noneconomic forces that provide positive explanations of farm size. In the space available for this paper, we have not explored important variants such as fixed supplies of some resources for the firm, absence of resource markets and prices, limited managerial resources which may cause certain types of scale economies and special merits of large units, differences in opportunity costs of capital for managers under different tenure forms, or objective functions that (a) differ between the cooperative and its individual members with their private plots and (b) maximize rent to the state rather than returns to members. These and other considerations should be brought into empirical or qualitative studies directed at explaining differences in farm size, between "capitalist" and "socialist" countries or between "developed" and "undeveloped" countries.

We hope that the discussion will go forward from this modest fundamental contribution to related problems which should be treated theoretically and quantitatively. For example, in the context of factor markets or relative scarcities and stages of economic development, larger farms in the East and smaller ones in the West also seem inconsistent (other social and political considerations aside). The reasoning is as follows, using production function (1) as a reference point: The least-cost combination of resources is denoted under the condition $\partial X_1/\partial X_j = P_j/P_1$ where P_j and P_1 are the respective prices or weights (reflecting and relative scarcities) of factors j and 1. If j denotes capital and 1 denotes labor, the optimal ratio of labor to capital will be smaller as the price of capital declines relative to the price of labor. Capital real price is lowest relative to labor at advanced stages of economic development and highest at lower stages of development. Countries at lower stages of development optimally should have a "high" ratio of labor to capital and those at higher stages of development should have a "low" ratio. However, as a greater amount and ratio of capital is used, the fixed costs of farming increase and the cost function declines over a greater magnitude of output (i.e., the minimum on the cost function occurs with a larger farm). In this context, since they are at a somewhat higher stage of economic development (the supply of capital

[5] If the production involved the "set-up" costs in (24) but otherwise was linear (i.e., if the term bR^2 were left off the function), there would be no limit to the optimal firm size for the individual farm if $a > (P_r + \alpha P_x)P_y$. Similarly, the average return per member (worker) on the cooperative farm would increase continuously with the magnitude of R, but a mathematical limit in return per worker (and thus in optimum size) is approached at the value $aP_y - \alpha P_x$ (the asymptote of average return is $aP_y - \alpha P_x$). If the function were $Y = e + aR - bR^2$, there would be a limit in optimum size for the individual farm, but as for (29) the pure cooperative farm would be "as small as possible" for a positive value of R.

is greater relative to the supply of labor), countries of Western Europe and North America should have a larger optimal farm size than countries in Eastern Europe. Since the opposite condition prevails and our previous analysis suggests that cooperative farms would never have an "individual optimal size" larger than a private farm (ceteris paribus), we have further reason for suggesting that more attention should be directed towards the analysis of optimal farm size under different tenure, social developmental structures.

Allocative Efficiency, Traditional Agriculture, and Risk*

JOHN L. DILLON AND J. R. ANDERSON

A decision theory approach is presented for the assessment of allocative efficiency from cross-section production function estimates. Reappraisal of some of the evidence previously adduced gives only mixed support to the hypothesis of profit-maximizing behavior by farmers in traditional agricultures. It is suggested that scope remains for investigation of the alternative hypothesis of utility maximization which, unlike profit maximization, explicitly allows for subjective risk considerations and might therefore provide a more realistic basis for policies aimed at the modernization of traditional agricultures.

WITH allocative efficiency defined in terms of profit maximization, T. W. Schultz's hypothesis that "there are comparatively few significant inefficiencies in the allocation of the factors of production in traditional agriculture" [20, p. 37] has been a topic of substantial interest in recent years. Major empirical studies relevant to the hypothesis have been the cross-sectional production function analyses of Chennareddy [2], Hopper [7, 8], Massell [10, 11], Massell and Johnson [12], Sahota [17], Welsch [22], Wise and Yotopoulos [24] and Yotopoulos [25, 26]. With the exception of Massell, whose presentation is noncommittal, these authors have concluded that their analyses support the hypothesis of profit-maximizing behavior in traditional agricultures.

Excluding the work of Wise and Yotopoulos, which constitutes a special case since it is oriented to individual firms rather than to the average sample firm, none of these studies has presented a test of *economic* merit or validity relative to Schultz's hypothesis. We believe more pertinent economic appraisals of the data relative to the average cross-sectional firm are possible and illustrate such an appraisal via some of the data previously adduced as supporting the hypothesis of profit maximization. Our reappraisal of these data provides only mixed support for the profit-maximizing hypothesis. The way is thus left open for investigation of alternative hypotheses—in particular, the hypothesis of allocative efficiency based on (expected) utility maximization in the face of subjective risk. Some discussion of this utility analogue of Schultz's hypothesis is presented after our reappraisal of the evidence for profit maximization.

The Usual Approach to Measuring Profit Maximization

The typical approach [2, 6, 8, 17, 22, 25] to judging efficiency in cross-sectional samples has been to estimate a Cobb-Douglas type production function and then, using point estimates of the production elasticities, to make some statistical sampling theory test of equality between the estimated single-valued marginal value products and marginal factor costs of the geometric mean firm. Such sampling theory tests then form the basis of statements like "All the [twelve] ratios except three are not significantly different from 1.0, indicating that available evidence does not lead to rejection of the hypothesis of production efficiency . . . Three of the ratios are significantly different from 1.0, . . . but two of them are significantly different from 1.0 only at the 10-percent level" [2, p. 891].

Such statements, based on the mechanical use of traditional significance levels, are devoid of economic content [5, Ch. 9; 18, Pt. 5]. In our view significance tests based on arbitrary probability levels are irrelevant to economic problems and provide no basis for the assessment of allocative efficiency. What is needed is a measure of profit-maximizing efficiency that has a direct economic interpretation yet depends on the statistical quality of the underlying production function estimate.

An Economic Approach to Measuring Profit Maximization

In essence, our approach for measurement of the degree of profit maximization is analogous to the use of opportunity loss functions in statistical decision theory [5, 27]. Given an estimate of a Cobb-Douglas production function, this approach involves estimating the expected opportunity loss of a producer who

* We are grateful to J. H. Duloy, B. J. Phillips, T. W. Schultz, D. E. Welsch, and P. A. Yotopoulos for critical comments, both those we have accepted and those we have not.

JOHN L. DILLON *is professor of farm management and* J. R. ANDERSON *is lecturer in economic statistics at the University of New England, Armidale, Australia.*

operates with the sample geometric mean combination of inputs rather than with the estimated most profitable combination of inputs. Recognizing the constrained situation under which producers generally operate, following Duloy [4] we define the optimal allocation as a fixed-outlay constrained optimum with the constraint set at the financial sum of the geometric mean resources. In other words, we examine the expected opportunity loss of the average input allocation relative to the most profitable allocation that is feasible with total expenditure unchanged.

As in the usual approach to measuring allocative efficiency, we take prices, technology, and entrepreneurial services as fixed and ignore the fact that these may vary among farms. Likewise, our analysis relates only to the average sample farm. As Massell and Johnson emphasize [12, p. 53], profit-maximizing resource use on the average farm is a necessary but not a sufficient condition for profit-maximizing behavior on individual farms. Concomitantly, any failure to meet profit-maximizing conditions on the average farm implies at least some failure to meet profit-maximizing conditions on an individual farm basis.

Consider the regression-based Cobb-Douglas type production function estimate from a cross-sectional sample:

$$Y = b_0 \Pi X_i^{b_i} \tag{1}$$

which relates income Y to the inputs X_1, $X_2, \cdots X_n$, each b_i being the best linear unbiased estimate of the population elasticity β_i. Costs of the inputs are introduced through the profit function:

$$\pi = Y - \Sigma c_i X_i \tag{2}$$

where c_i is the unit price of X_i.

Opportunity loss L incurred by nonoptimal operation of the average firm is defined as

$$L = \tilde{\pi} - \bar{\pi} \tag{3}$$

where $\tilde{\pi}$ and $\bar{\pi}$ denote respectively the profit computed at the optimal and geometric mean input levels (denoted by $\tilde{X}_i$ and $\overline{X}_i$ respectively). Since optimal operation is constrained to employing only the geometric mean total of resource outlay (i.e. $\sum c_i\tilde{X}_i = \sum c_i\overline{X}_i$), this opportunity loss can be expressed as

$$L = b_0(\Pi \tilde{X}_i^{b_i} - \Pi \overline{X}_i^{b_i}). \tag{4}$$

The loss L will be zero if $\overline{X}_i$ equals $\tilde{X}_i$ for all i, and positive otherwise.

The measure by which we propose judging efficiency of resource use is the expectation of the opportunity loss L when account is taken of the fact that the production coefficients b_i are probabilistic estimates based on data from a cross-sectional sample reflecting nonhomogeneity due to variations in resource endowments, weather effects, and managerial services and attitudes. Thus the question we pose is: What is the expected opportunity loss suffered by a geometric mean producer relative to the expected profit he would achieve if he were to operate at the constrained optimal input levels implied by the b_i, given that these b_i are only sample estimates and have some associated probability distribution?

For any estimated production function, the loss L is a function of the random variables b_i denoted by $L(b_1, b_2, \cdots b_n)$. If we denote the joint probability distribution of the b_i's by $f(b_1, b_2, \cdots b_n)$, the expected loss is

$$EL = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty}\cdots\int_{-\infty}^{\infty} L(b_1, b_2, \cdots, b_n) \cdot f(b_1, b_2, \cdots, b_n)\,db_1 db_2 \cdots db_n. \tag{5}$$

Because of the algebraic form of $L(b_1, b_2, \cdots b_n)$, it is computationally most expedient to estimate EL by Monte Carlo evaluation of the integral of equation (5) using pseudorandom sampling from the appropriate multivariate distribution of the b_i's. That is, a sample of b_i's is drawn at random, the associated loss computed as in equation (4), and this procedure repeated many times so that the average of these losses approaches EL stochastically. Following the usual assumptions, the multivariate normal is suggested with the proviso that variates are truncated symmetrically so that sampled b_i's are strictly positive, as is required by economic theory. Empirical work indicates that 1,000 replications of the Monte Carlo procedure are sufficient to provide a stable estimate of EL.

An index by which the degree of nonattainment of profit maximization by the average firm may be subjectively assessed is given by the ratio of expected loss to expected optimal profit, i.e., $EL/E\tilde{\pi}$ $(=EL/[EL+E\bar{\pi}])$. The greater the divergence of this ratio above or below zero, the greater the degree of inefficiency implied by operation at geometric mean input levels.[1] Multiplying the absolute value of the

[1] Just what size index of inefficiency should be interpreted as implying significant nonattainment of profit maximiza-

ratio by 100 gives the percentage of potentially achievable profit foregone through failure to allocate resources optimally in terms of profit maximization.

Some Evidence Reexamined

Because the published studies of interest [2, 8, 10, 11, 12, 17, 22, 25, 26] do not report the covariance matrix of the b_i's and because our further attempts to obtain this information were unsuccessful, it was necessary to simplify equation (5) by using the marginal probabilities of the joint distribution of the b_i's. This is equivalent to assuming that the distributions of the individual b_i's are independent.[2]

A further difficulty was that some or all of the required data concerning prices and geometric mean input levels were not available for the studies of Massell [10, 11] and Welsch [22] so that reappraisal of these studies was not possible. Likewise, it was decided not to reprocess Sahota's [17] functions because of the number of variables and production functions involved and because of some doubts about the underlying data which (unlike that of the other studies) were not collected specifically for the purpose of testing the hypothesis of profit maximization. Our reappraisal of the evidence therefore relates only to the samples of Chennareddy [2] for South India; Yotopoulos [25, 26] for northern Greece; and on an enterprise-by-enterprise basis, Hopper [8] for North Central India.

Chennareddy data

Three production function estimates were presented by Chennareddy in support of the profit-maximizing hypothesis. They relate to farms in the West Godavari district of South India: one for a sample of 67 rice farms, one for 37 tobacco farms, and a "district" function based on aggregation of the rice and tobacco samples. The input categories were land, labor, capital, and operating expenses.

Table 1. Expected loss and index of inefficiency of operation at average input levels for three South Indian production functions[a]

	Sample		
	Rice	Tobacco	District
Expected loss, EL (Rs.)	265.5[b]	2,757.3	238.5
Index of inefficiency, $EL/E\bar{\pi}$	0.13[b]	0.28	0.10

[a] Chennareddy [2].
[b] With nonland capital held at its mean level.

Table 1 lists the results of our analysis. The prices used were those specified by Chennareddy. Because of the very poor estimate of the coefficient for nonland capital in the rice sample function (0.0001 with standard error 0.0482), nonland capital was held fixed at its geometric mean level in calculating expected loss for the rice sample. Thus the estimate of expected loss for rice must be regarded as only a partial estimate, since it assumes one of the production coefficients to be known perfectly and therefore underestimates potential expected loss. Too, because of the influence of the rice sample component, the capital coefficient in the district function (0.0007 with standard error 0.0273) is rather unreliable, so that the results for the tobacco sample must be regarded as the most reliable of the three efficiency analyses. Given these provisos, the expected losses of Rs. 265 and 238 and indexes of inefficiency of 0.13 and 0.18 for the rice and district functions, respectively, imply fair correspondence with the hypothesis of profit maximization. The reverse applies to tobacco and suggests a conclusion rather different from that drawn by Chennareddy. For the tobacco sample he found that none of the MVP/MFC ratios differed significantly from unity at the five percent level and concluded that resources were allocated in profit-maximizing fashion.[3] With an index of inefficiency of 0.28, implying an expected opportunity loss equal to 28 percent of potentially achievable expected profit, we are forced to draw the alternative conclusion that allocative efficiency in this traditional agriculture is low in terms of profit maximization.

tion is a matter of subjective judgment. No standards of comparison are yet available. Personally, we feel that an index greater than $|0.2|$ (i.e., more than 20 percent of potentially achievable profit foregone) may reasonably be interpreted as indicating poor allocative efficiency with respect to profit maximization. Others may differ in their judgment.

[2] The extent and direction of bias in estimates of EL resulting from the assumption of zero covariances between the b_i's depend on several factors including the correlations among the independent variables. Often the variables will be positively intercorrelated, in which case the covariances between the b_i's will tend to be negative so that a failure to account for covariance may tend to overestimate EL. The extent of overestimation will depend on all the numerical features of a production function.

[3] The ratio for district capital in Chennareddy's Table 2 [2, p. 819] is misprinted; it should read 0.071.

Yotopoulos data

The evidence presented by Yotopoulos relates to a sample of 430 subsistence farmers in the Epirus region of northern Greece. His study, by far the most thoroughgoing of those so far addressed to the efficiency of traditional agriculture, is comprehensively described in [25]. Analysis pertinent to the hypothesis of profit maximization is summarized in [26].

Yotopoulos hinges his discussion of profit-maximizing efficiency on his Cobb-Douglas function *R*2 [26, p. 129], which includes an education variable and combines data from both large and small farms. He finds land and labor to be allocated very efficiently on the average farm. The position with regard to the three capital input classes and the education variable is not so clear. The difficulties in assessing capital use arise from the definitions of the service flows used to measure capital inputs. These make pricing of these inputs somewhat ambiguous [26, p. 131]. It seems likely that the true opportunity cost of capital lies within the range of 1.05 to 1.15 drs. per dr. Assuming a cost of 1.10 drs., the allocations of plant and equipment capital seem quite efficient in conventional terms, and the use of live capital rather less efficient. Efficiency in the use of education could not be assessed because of the lack of data on its marginal cost. Overall, Yotopoulos [25, Ch. 11; 26, p. 133] concludes that the traditional agriculture of Epirus is "poor but efficient."

In our reexamination of his data, we used Yotopoulos' function *R*2 with education held fixed at the sample geometric mean level, thereby treating one of the coefficients as known perfectly with a consequent reduction in potential expected loss. The marginal costs assumed for labor and land were 29 drs. and 90 drs. respectively as per Yotopoulos [26, pp. 130–1]. Because of difficulties already noted in pricing capital, three values were used: 1.05, 1.10, and 1.15 drs. per dr. Our results, listed in Table 2, are quite insensitive to the capital price variations considered. They indicate that the average Epirus farmer was sustaining an expected opportunity loss equal to eight percent of his potentially achievable expected profit. This result well supports the hypothesis of profit maximization in the traditional agriculture of Epirus.[4]

[4] In further analysis of Yotopoulos' data, using a model that allows for interfirm variation in productivity and prices, Wise and Yotopoulos [24] have found that on an individual (rather than average) farm basis, two-thirds of the variance in input use could be explained by profit maximization. They do not mention the alternative hypothesis of expected utility maximization.

Table 2. Expected loss and index of inefficiency of operations at average input levels for a Greek production function[a] under three costs of capital

	Cost of capital[b]		
	1.05	1.10	1.15
Expected loss, *EL* (drs.)	1,131	1,090	1,206
Index of inefficiency, $EL/E\bar{\pi}$	0.08	0.08	0.08

[a] Yotopoulos [26].
[b] Drachmas per drachma.

Hopper data

Based on a sample of 43 farmers in an Uttar Pradesh village, Hopper [8] estimated separate production functions for their dry season barley, wheat, pea, and gram enterprises. These crops are highly competitive in their demands for the farmer's inputs of land, labor, bullock time, and irrigation water. Data on input use were meticulously collected relative to each crop. In terms of economic appraisal, an inherent difficulty was the poor definition of the factor markets—particularly for land, bullock time, and irrigation water. These difficulties were noted by Hopper [8] and by Schultz [20, pp. 44–48] who, in advocacy of his hypothesis, made extensive use of Hopper's results.

Following Hopper [8, p. 621], labor was priced at Rs. 0.068 per hour in our reappraisal, and, in the absence of a well-defined market for irrigation water, a 750-gallon unit was costed approximately [8, p. 623] at Rs. 0.5. For the price of bullock time we used Rs. 0.76, the implicit equilibrium price estimated by Hopper [8, p. 621]. Choice of an annual charge for a "standard" acre presented more difficulty since the tenants' payment for land typically consisted of a cash rent plus a variety of nonmonetary "understandings," such as the provision of labor when required by the landlord [8, p. 622]. We straddled the likely range of annual land price by using prices of Rs. 13, 36, 45, 59, 83 and 106. Rs. 13 corresponds to the average annual cash rent for a standard acre, as reported by Schultz [20, p. 95] from Hopper [7].

Rs. 106 corresponds to an interest rate of 4.5 percent on the market value of a standard acre. Based on these input prices, the expected losses of a geometric mean producer for each of Hopper's estimated production functions are summarized in Table 3 and Figure 1.

As Figure 1 shows, minimum expected loss for each crop enterprise considered independently[5] occurs at a land price of Rs. 36 for peas and at Rs. 45 for barley, wheat and gram. Except for the pea enterprise, these loss minimizing prices are consistent both with each other and with Hopper's alternative point estimates of Rs. 44 and 48 for the implicit equilibrium land price [8, pp. 620–1]. If the actual average price of land were in fact Rs. 45 and our other assumed prices were equilibrium (i.e., loss-minimizing) prices for the average firm, then our analysis would strongly support Schultz's hypothesis. We do not, however, know the price paid for land and, as Figure 1 shows, the assumed prices for other factors can not be equilibrium prices relative to geometric mean input levels since they do not permit an expected opportunity loss of zero. For these reasons the inefficiency indices of Table 3, indicating expected opportunity losses at best of only 6 to 11 percent of potentially achievable profit, must be regarded cautiously. All that can be said from our analysis is that the possibility of profit-maximizing behavior by the average producer is not disproved. Such would have been the case if the expected loss-minimizing land price had differed markedly among the four crops (given their competitive demand for resources) and if expected losses at these prices had been close to zero. Thus, because of the lack of definition of the factor markets, our reappraisal of Hopper's data is inconclusive. The same difficulty, however, is also implicit in the analyses of Hopper [8] and Schultz [20, pp. 44–48].

[5] Independent assessment based on a fixed outlay constraint for each crop rather than interdependent assessment of all four enterprises with only an overall constraint on outlay [3, pp. 60–2] was used so as to obtain the implicit loss-minimizing land price for each crop.

Table 3. Expected loss and index of inefficiency of operation at average input levels for four Central Indian production functions[a] under three land prices

	Enterprise			
	Barley	Wheat	Pea	Gram
Land price = Rs. 13				
Expected loss, EL (Rs.)	168.1	49.6	144.2	41.1
Index of inefficiency, $EL/E\bar{\pi}$	0.21	0.14	0.22	0.15
Land price = Rs. 45				
Expected loss, EL (Rs.)	79.2	23.8	72.4	18.8
Index of inefficiency, $EL/E\bar{\pi}$	0.09	0.06	0.11	0.06
Land price = Rs. 106				
Expected loss, EL (Rs.)	119.5	50.8	138.2	43.1
Index of inefficiency, $EL/E\bar{\pi}$	0.15	0.14	0.20	0.14

Utility Versus Profit Maximization

Our reappraisal of some of the evidence, using an economic (decision theory) rather than a statistical (significance testing) criterion of profit-maximizing efficiency, gives only mixed support to the hypothesis of profit-maximizing behavior by farmers in traditional agriculture. We find Yotopoulos' data relatively favorable to the hypothesis, Hopper's data inconclusive, and Chennareddy's data relatively unfavorable.

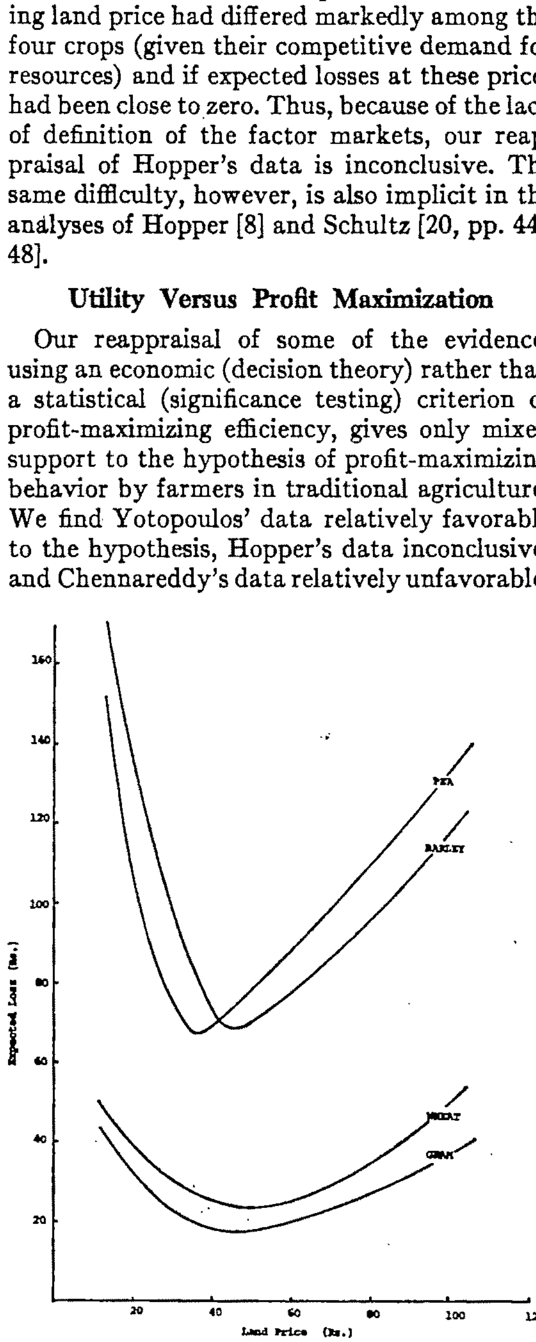

Figure 1. The effect of varying price of land on expected losses for four Central Indian production functions

Nonetheless, our results are more favorable to the hypothesis of expected profit maximization than we would have expected. Personally, we would hypothesize that farmers in traditional agriculture (and elsewhere) typically have nonlinear utility functions (implying active consideration of subjective risk) and successfully endeavour to maximize expected utility[6] rather than expected profit. Such a hypothesis would be compatible with our results if it could be assumed that the average Epirus farmer had a nearly linear utility function and saw himself as facing little risk. But there is no available evidence to support such assumptions. In contrast, no special assumptions are needed in suggesting that our analysis of the Chennareddy and Hopper data leaves the way open for investigation of the alternative hypothesis of utility maximization.[7] Some comments on the utility hypothesis are therefore pertinent, particularly since the usual literature on agricultural development (e.g. [13, ch. 16; 14, 19, 20]) advocates the profit-maximizing hypothesis and contains only passing comment on risk considerations. Moreover, these comments are generally qualitative, invariably emphasize risk aversion, ignore utility, and are largely based upon introspection. The same is true of the limited literature specifically concerned with risk in underdeveloped agricultures.[8]

So far as we are aware, the quantitative evidence on the role of risk in traditional or developing agricultures is very limited. Behrman [1, ch. 10], in his study of Thai crop supply response, found negative response in aggregate to increasing risk. In a recent unpublished study of the utility functions of producers in the traditional wool-growing industry of the Australian pastoral zone, Francisco and the authors found 20 members of a sample of 21 producers to have nonlinear utility functions, 3 of which exhibited risk preference. Vicente [21], in a study of 47 Chilean farmers' utility functions over the range of money gains to three times their annual net income, found only 4 functions to be approximately linear and 12 to exhibit strong risk preference.

Though probably explainable in the context of the state-financing and uncertainty surrounding the Chilean land reform, the extent of risk preference found by Vicente is particularly interesting. It runs counter to the accepted wisdom about risk found in much of the agricultural development literature, e.g., [13, 14, 20, 23]. This wisdom runs somewhat as follows (overlooking the inconsistency of implying both profit and utility maximization): (1) traditional agriculture is efficient in a profit-maximizing sense; (2) development necessitates new techniques and inputs; (3) new techniques and inputs are viewed by farmers as risky; (4) farmers are risk averse; (5) risk is therefore an important impediment to development. Such a line of argument may overemphasize risk aversion. Attitudes to risk, as measured by the degree of preference or aversion, will vary both among farmers and, for one farmer, among different levels of expected profit. We would hypothesize that risk is not a negative influence for all producers and that attitudes of risk preference may have, for example, played an important role in catalyzing the recent rapid adoption of new crop varieties in some parts of Asia.

Finally, despite the mixed results of our reappraisal of the Chennareddy, Hopper, and Yotopoulos data, in our view quantitative information on risk attitudes must be an important element in understanding farmer behavior in underdeveloped agricultures and, ipso facto, in the generation of policies for their modernization. Such quantitative information could be readily obtained via the estimation of farmers' utility functions [9, 15]. At the same time, as suggested by Wharton [23], much more attention should also be given to quantitative assessment of the subjective risks seen by farmers in underdeveloped agricultures. With better knowledge of both farmers' attitudes to risk and the risks they see themselves facing, it should be possible to formulate more efficacious development policies. Such opportunities could be lost if the hypothesis of profit maximization is accepted without qualification.

[6] This hypothesis is not new. It was argued more than a decade ago by Porter [16] in a theoretical paper concerned with risk aversion as an impediment to technical change in Indian agriculture. Porter also explored in some detail the possible policy implications of the expected utility hypothesis. Regrettably, this work appears to have been overlooked in more recent analyses of efficiency in traditional agriculture.

[7] Testing of the utility hypothesis is likely to be difficult since each producer must be postulated to have his own individual utility function and it makes no sense to talk of an aggregate or sample utility function. Appraisal would have to be on an individual producer basis, perhaps along the lines suggested by Officer and Halter [15].

[8] This literature has been noted in a comprehensive paper by Wharton [23].

Economic Analysis of Irrigation in Subhumid Climate*

Oscar R. Burt and M. S. Stauber

An economic model is developed for analysis of investments in irrigation. The model encompasses the associated problem of temporal allocation of limited irrigation water within the growing season of a single crop. The problem is placed in the framework of stochastic dynamic programming, and it is shown how the algebraic form of the production function for the crop determines the appropriate state variables of the decision process. An application of the model is made to conditions prevalent in Central Missouri with corn the irrigated crop.

Recent technological developments have stimulated interest in the economic feasibility of irrigating field crops in relatively high precipitation areas. Intensification in the production process has taken place by increasing the levels of many factors while holding inputs of water constant at natural precipitation, which tends to increase the marginal productivity of water (assuming complementarity among the factors of production with water). Also, technological improvements in the methods of pumping and distributing water, as well as improvements in earth-moving equipment used to prepare irrigation sites and reservoirs, have extended the boundaries of economic feasibility. Consequently, an economic evaluation of the feasibility of investments in irrigation facilities in subhumid areas assumes increasing importance.

Irrigation development in subhumid areas is likely to be dominated by individual farm or relatively small community developments as contrasted to the large reclamation projects characteristic of arid regions. In subhumid regions, runoff from each farm is often adequate to provide supplemental irrigation water for the limited irrigable land on the farm, although there are many situations that could benefit from community-coordinated irrigation development where the runoff can be captured more efficiently for larger areas. Government may have a responsibility stemming from externalities associated with irrigation development, but the inherently small-scale investments will be left up to individuals or, at most, to small groups of farmers. However, subsidies such as those administered by the Soil Conservation Service might be important in motivating private development. Since most investment decisions on irrigation in subhumid regions will be made by the private sector, this study focuses on decision problems confronted by the individual or by a small group that functions essentially as a single decision unit.

The Investment Decision

Determination of an efficient investment policy in irrigation facilities can be viewed as ascertaining the optimal allocation of limited funds to the various investment categories comprising a workable irrigation system. More specifically, an investment model can be defined with three components, or variables, to which funds are devoted:

x = water storage capacity
y = distribution capacity
z = acres developed for irrigation

The net cash flow, or quasi-rent, associated with an investment and received in year t is denoted by $N_t(x, y, z)$, and initial cost of the investment is denoted $I(x, y, z)$. Replacement and maintenance costs are deducted in the definition of $N_t(x, y, z)$. This quasi-rent function, $N_t(x, y, z)$, is a critical measure for economic evaluation of investments in irrigation, and it is extremely difficult to estimate in subhumid climates. In the first place, quasi-rents are random variables with substantial variation, which suggests that $N_t(x, y, z)$ be defined as an expected value instead of actual quasi-rent. Also, there is implicitly an intraseasonal irrigation policy associated with the definition of quasi-rents. A major objective of this article is to develop and illustrate the methodology for deriving *optimal* irrigation policies, which are necessary to make an economic analysis of irrigation investments. Thus $N_t(x, y, z)$ is defined as an expected value measure and implicitly reflects an optimal irrigation policy for intraseasonal management of water, given an

investment described by the magnitudes of x, y, and z.

If the money capital position of the firm is such that the present value criterion can be applied, the investment problem can be stated as

$$\text{(1)} \qquad \underset{x,y,z}{\text{Maximize}} \left[-I(x, y, z) + \sum_{t=1}^{T} N_t(x, y, z)/(1 + r)^t\right]$$

where T is the firm's planning horizon and r is the relevant discount rate. Terminal value of the investment at the end of the firm's planning horizon is included in $N_T(x, y, z)$. Necessary conditions for (1) to be a maximum are: marginal initial investment costs equal discounted marginal quasi-rents with respect to each variable. In some situations, or for simplification of the analysis, y may be uniquely determined for given values of x and z, which lets it be dropped from the problem as a decision variable.

More often than not money capital is limiting and its opportunity cost is unknown, or more specifically, the opportunity cost must be jointly determined with the optimal allocation of the limited funds. The internal rate of return is a useful guide in such circumstances. Let the limited capital for investment in irrigation be $\$C$. The decision problem is to allocate it among the three components x, y, and z so that the internal rate of return is a maximum. This is stated mathematically as the maximization problem of (1) subject to the constraint

$$\text{(2)} \qquad I(x, y, z) = C$$

and the auxiliary equation

$$\text{(3)} \qquad I(x, y, z) = \sum_{t=1}^{T} N_t(x, y, z)/(1 + r)^t$$

which determines r simultaneously with x, y, and z. The necessary conditions are expressed by the four equations: (2), (3), and the two equations in (4).

$$\text{(4)} \qquad \left[\sum_{t=1}^{T} \frac{\partial N_t}{\partial x} \Big/ (1 + r)^t\right] \Big/ \frac{\partial I}{\partial x} = \left[\sum_{t=1}^{T} \frac{\partial N_t}{\partial y} \Big/ (1 + r)^t\right] \Big/ \frac{\partial I}{\partial y} = \left[\sum_{t=1}^{T} \frac{\partial N_t}{\partial z} \Big/ (1 + r)^t\right] \Big/ \frac{\partial I}{\partial z}.$$

The two equations in (4) have the interpretation of equal ratios of discounted marginal quasi-rents to marginal initial investment costs among all pairs of investment components, x, y, and z.

For a given developed acreage and at a particular point in the irrigation season, either water supply as determined by x or distribution capacity, y, may limit the total amount of irrigation water applied. Distribution capacity will be a limitation predictable with certainty, but for a given storage capacity the water supply constraint will be a random variable when looking ahead more than one period at a time. Taking x and y as a composite dimension of the investment decision and acres developed, z, as the other variable, the critical question in the investment decision is whether to irrigate a few acres intensively or many acres extensively. When average precipitation is fairly heavy, but extremely variable as in most subhumid areas, this is not an easy question to answer. The intraseasonal irrigation policies applied under various levels of intensity of irrigation are indispensable in estimating the quasi-rent functions. The fact that very little research has been done to determine efficient intraseasonal irrigation policies may be a serious bottleneck in estimating the quasi-rent functions and thus objectively evaluating irrigation investments.[1]

Temporal Allocation of Irrigation Water

The temporal allocation problem to be discussed here exists under irrigation in arid as well as subhumid regions, but the analysis is more complicated in higher precipitation areas because of the increased importance of random precipitation. A significant amount of precipitation during the growing season of the crop accentuates the importance of a sequential decision framework that exploits all the information known at each point in time. The problem is to find a sequential decision rule that maximizes an appropriately defined objective function taking into account the stochastic nature of precipitation and other pertinent random weather inputs.

Bellman [1, 2, 3] has helped to develop the theory of multistage or sequential decision processes and has coined the term dynamic pro-

[1] Since this study was completed, there have been several other studies addressed to the problem of intraseasonal allocation of limited irrigation water [6, 10, 13]. The dissertations of de Lucia [6] and Dudley [10] also consider some aspects of the investment decision problem.

gramming to describe the methodology that will be used on the temporal distribution problem of irrigation water. Some basic concepts and definitions that are needed to understand dynamic programming procedures are discussed in the context of their general application to an irrigation problem. First, the decision process or economic activity is divided into time periods or intervals, called *stages*. The *state* of the process is another important concept. For crop irrigation, the state variables should describe the condition or productive potential of the crop and the availability of water stocks, both of which are dependent upon past weather conditions and irrigation treatments.

At each stage a set of relevant decisions or alternative actions exists concerning the amount of water to apply, if any. Selection of a particular alternative at a specified stage and state of the process will influence the state of the process in the following stage. This introduces the concept of *state transition*. Transition from one state to another can be with certainty, or it can be stochastic in nature. With supplemental irrigation the transition is stochastic, because of the uncertain nature of random weather inputs, such as precipitation and temperature, which influence crop condition and water stocks.

An optimal policy specifies the decision, for all possible combinations of states and stages, that will result in optimization of the criterion function. In the context of a supplemental irrigation process, the optimal policy would indicate the amount of water to apply at each time period, for all possible combinations of crop conditions and levels of water supply, in order to maximize expected net returns.

A general requirement must be placed on the criterion function in order to apply dynamic programming. This requirement, known as Markovian dependence [1, p. 54], states:

> After any number of decisions, say k, we wish the effect of the remaining N-k stages of the decision process upon the total return to depend only upon the state of the system at the end of the k-th decision and the subsequent decisions.

That is, at each stage the decision process is independent of earlier stages, provided the state of the process is given. This property in the context of an irrigation problem means that the state variables of the process must encompass the complete influence of all factors affecting the crop in previous stages; and for a given stage and state of the process, only the decisions in the current stage and future stages determine an optimal policy.

In many respects the greatest challenge in applying dynamic programming is to formulate a realistic model with the state variables defined in such a way that the Markovian condition is met and the number of state variables is small, preferably no more than two.

The temporal allocation problem, in its broadest framework, has two distinct parts: (1) intraseasonal or short-period allocation, which is always important; (2) interseasonal or annual allocation of water, which becomes less important under relatively high annual precipitation, when irrigation has the primary function of redistributing water within the year to increase production and total water during most years is adequate without carryover from preceding years. Of course, the importance of annual carryover is relative, and there is always a chance that carryover would be advantageous during some years even under very high average precipitation.

Only the first of these two allocation decisions is analyzed in this study, in which it is assumed that year-to-year carryover is relatively unimportant. The present model is also applicable when the water supply is ground water or a stream without storage, in which case the state variable for water storage is deleted from the model.

The simplifying assumption is made that additions to the storage reservoir during the irrigation season are negligible; or, as an approximation, expected additions to storage in that period are treated as if already in storage. This assumption should cause little concern when applied to subhumid areas such as eastern United States, because their irrigation season is both short and *relatively* dry compared with winter and early spring.

The crop production function

The algebraic form of the production function, which contains climatic and cultural variables as its arguments, determines the number and form of state variables used to describe crop condition at a particular stage of the decision process. For practical purposes the production function must not only be a good statistical fit; it must also be amenable to partitioning in the time dimension using only one or two state variables.

To clarify the nature of the problem, let us examine the Cobb-Douglas function with only water as an argument. The irrigation season is

divided into M discrete time periods, and water added to the soil during each period is a separate factor of production. Let irrigation water and precipitation be denoted, respectively, by u_j and v_j for the jth period of the season; and irrigation water is a net measure commensurate with precipitation so that a composite water variable, $w_j = u_j + v_j$, can be defined. The Cobb-Douglas function is written as

$$(5) \qquad Y = b_0 w_1^{b(1)} w_2^{b(2)} \cdots w_M^{b(M)},$$

where b_0 and $b(i)$ are parameters. The partial yield factor

$$(6) \qquad b_0 w_1^{b(1)} \cdots w_j^{b(j)}$$

summarizes the influence of water (irrigation and precipitation) received during the first j periods of the irrigation season. If we were given the above factor (6), we could compute yield for any set of water variables, w_{j+1}, $w_{j+2}, \cdots w_M$. In other words, (6) summarizes the influence of $w_1, w_2, \cdots w_j$ on yield with only a single measurement. That measurement could serve as a state variable in a dynamic programming formulation.

However, we could also use any monotonic transformation of the yield equation instead of the equation itself. A monotonic transformation permits a one-to-one correspondence between yield and the transformed yield. Thus, taking logarithms of both sides of (5) gives

$$(7) \qquad \log Y = \log b_0 + b(1) \log w_1 + \cdots + b(M) \log w_M.$$

All the influence of water on the crop through period j can now be summarized by the partial sum

$$(8) \qquad b(1) \log w_1 + b(2) \log w_2 + \cdots + b(j) \log w_j,$$

which could serve as an alternative to (6) as a state variable when yield is expressed by (5).

In contrast to a single state variable being sufficient, a general quadratic in $w_1, w_2, \cdots w_M$ would require a state variable for each w_i, $i \leq j$, to summarize the influence of $w_1, w_2, \cdots w_j$ on yield. Thus, at the beginning of period $j+1$ the quadratic would force us to use j state variables to measure crop condition, while the Cobb-Douglas would require only one state variable.

A functional form that has proved versatile and effective in explaining crop yields for the authors is the following general class of functions:

$$(9) \qquad \psi(Y) = h\left(\sum_{i=1}^{M} \phi_i(W_i) \right),$$

where Y is crop yield and W_i is a vector of climatic and cultural variables (including irrigation) to which the crop was subjected during period i. The function ψ is a monotonic transformation of yield, while h and ϕ_i are completely arbitrary functions. Most of the authors' work has been with untransformed yield and h and ϕ_i polynomials, although small grain yields have been successfully analyzed with exponential and logarithmic forms of h and ϕ_i.

An equation used by Doll [9, p. 82] is a special case of (9), where h is quadratic and ϕ_i is linear. The Cobb-Douglas also falls in this class of functions, as can be seen by comparing (7) with (9). The "constant elasticity of substitution" production function, which is currently popular in analyzing aggregate economic data, is also included under (9).

Equation (9) requires only a single state variable and has the virtue of relatively few parameters in most cases. The state variable is the partial sum $\phi_1(W_1) + \phi_2(W_2) + \cdots + \phi_j(W_j)$. With this background on the role of production functions in defining state variables, we are ready to formulate the dynamic programming model for irrigation.

The dynamic programming model

The assumptions of negligible additions to storage during the irrigation season and a zero value to water in storage at the end of the irrigation season permit a per acre formulation that greatly simplifies the investment decision. Storage capacity, water applied, etc., are specified on a per-acre basis.

The following formulation uses only precipitation as a climatic variable in the production function, but the application given later in the paper includes temperature and precipitation jointly. The objective here is to present the logic of the method without cluttering the exposition.

The usual convention of dynamic programming will be used in which stages are counted from the end of the planning horizon instead of the beginning. The relationship between stages of the decision process and time periods is portrayed in Figure 1. Note that stage M is first period in the irrigation season, stage 1 is the last period in which irrigation water might be applied, and stage 0 is the harvest or gross valuation period.

The following notation and definitions are

time	1	2	· · ·	M−1	M	M+1	
stage	M	M−1	· · ·	2	1	0	

Figure 1. Chronological time contrasted with stages of the decision process

made. The stage of the process is denoted by superscripts, with the index n implying a particular stage, $n=0, 1, \cdots M$. Water is measured in inches per acre.

- s_1^n = a partial sum of terms from the production function which measures "crop condition";
- s_2^n = water in storage;
- u^n = net irrigation water applied (the decision variable);
- v^n = precipitation;
- $G(u^n)$ = gross amount of water that must be withdrawn from storage or pumped;
- $c(u^n)$ = expected costs associated with the decision to apply u^n units of water;
- D = distribution or pumping capacity (per acre);
- $f^n(s_1^n, s_2^n)$ = expected net returns from an n-stage process under an optimal policy when the initial state is that defined by s_1^n and s_2^n (the criterion is maximum expected value of net returns), $n=1, 2, \cdots M$;
- $f^0(s_1^0, s_2^0) = R(s_1^0)$, the net harvest value of the crop.

The formulation is made with the production function of (9), and the climatic vector W is assumed to have only a single component which is the sum of precipitation and net irrigation water denoted by w. The variables are redefined by stages, so that (9) is rewritten

$$\psi(Y) = h(\phi^M(w^M) + \phi^{M-1}(w^{M-1}) + \cdots + \phi^1(w^1)), \tag{10}$$

where $w^n = u^n + v^n$.

The state variable transformation functions are

$$\begin{aligned} s_1^M &= 0 \\ s_1^{n-1} &= s_1^n + \phi^n(u^n + v^n), \\ &\qquad n = M, M-1, \cdots, 2, \\ s_1^0 &= h(s_1^1 + \phi^1(u^1 + v^1)) = \psi(Y), \end{aligned} \tag{11}$$

$$\begin{aligned} s_2^{n-1} &= s_2^n - G(u^n), \\ G(u^n) &\leq s_2^n, \quad n = M, M-1, \cdots, 1. \end{aligned} \tag{12}$$

Equations (11) should be clear from the production function (10). Starting at $n=M$ and iterating, we see that

$$s_1^{n-1} = \phi^M(u^M + v^M) + \cdots + \phi^n(u^n + v^n), \quad n = M, M-1, \cdots, 2,$$

which is merely a partial sum of the terms in the production function. Transition to the last stage finishes the sum and ties the additive components together with the function h. The terminal value function $R(s_1^0)$ then assigns a net harvested value to the transformed yield $\psi(Y)$.

The last transformation, equation (12), is obvious since water in storage next period is what there was this period minus withdrawal this period, which cannot be more than was in storage. Recall the assumption of no additions during the irrigation season. Initial storage at the beginning of the irrigation season, s_2^M, will be some known number.

Sufficient basis has now been laid to make the dynamic programming formulation complete with the recurrence equation:

$$\begin{aligned} f^1(s_1, s_2) &= \operatorname*{Max}_u \left[-c(u) + Ef^0(h(s_1 + \phi^1(u + v^1)))\right] \\ f^n(s_1, s_2) &= \operatorname*{Max}_u \left[-c(u) + Ef^{n-1} \cdot (s_1 + \phi^n(u + v^n), s_2 - G(u))\right], \\ &\qquad n = 2, 3, \cdots, M, \end{aligned} \tag{13}$$

subject to the constraints

$$G(u) \leq s_2$$
$$u \leq D$$

The superscripts denoting stage have been deleted from s_1, s_2, and u to simplify the equations, but each is implicitly the variable associated with stage n. The expectation operator is denoted by E.

Solution methods for (13) are given in [3]. Basically, the procedure is to solve for the entire equation $f^1(s_1, s_2)$ by numerical methods, then solve for $f^2(s_1, s_2)$, and so on until $f^M(s_1, s_2)$ is obtained. A unique feature of dynamic programming is that solutions are obtained for the entire state variable space, i.e. all pairs of values for s_1 and s_2. This is of no consequence for s_1, which always begins stage M (first period of the irrigation season) at the same

level, namely zero. But the second state variable is water in storage, and for a given size reservoir the probability distribution for initial storage could be computed.

An Integration of the Investment and Temporal Allocation Models

Let us define a new function:

$$(14)\quad g(s_2, D) = f^M(0, s_2), \qquad \text{for given } D.$$

Equation (14) is expected net returns per acre under an optimal irrigation policy for an initial amount of water in storage per acre of s_2 and distribution capacity of D units of water per acre.

Going back to the investment decision model, total storage is x, distribution capacity is y (not to be confused with crop yield), and number of acres developed is z. First, we note that acres considered for irrigation in a given year need not be z but can be something less, say $A \leq z$. Denote total water in storage at the beginning of the season as S; then $s_2 = S/A$ for a given year. Total expected returns for the year, given S, A, and y, are $g(S/A, y/A)A$ since $D = y/A$. We can thus make a conditional optimization,

$$(14\text{a})\quad \max_{A \leq z} g(S/A, y/A)A = g^*(S, y, z),$$

for any given value of S.

But S is a random variable that contains x as a parameter in its probability density function. Taking the expected value of $g^*(S, y, z)$ with respect to S for given x, we get a function

$$(14\text{b})\quad \bar{g}(x, y, z) = Eg^*(S, y, z).$$

After adjusting $\bar{g}(x, y, z)$ for replacement and maintenance costs of the investment components in irrigation, we obtain the quasi-rent functions $N_t(x, y, z)$. This completes the methodological part of the study, and an application to corn irrigation in Missouri follows.

Application to Corn Irrigation in Central Missouri

The mathematical model just formulated was used to analyze the economics of corn irrigation in central Missouri, primarily to provide results that could be applied to evaluate investments in irrigation at the farm level. Since the model is structured on a per acre basis, its results are applicable to diverse farm situations. Hence, experiment station research conducted with the per-acre model can be utilized with a minimum of specialized analysis at a given farm site.

The production function for corn

Space does not permit a detailed discussion of the problems associated with estimation of a yield response surface for corn when climatic variables are included as explanatory variables. The task is complicated by the many variables involved and their apparent nonlinear influence on yield. Technically, the magnitude of each daily climatic factor is a separate explanatory variable, but many simplifications are necessary to make statistical estimation feasible. A minimum number of climatic factors must be included in the response function since precipitation in subhumid areas provides part of the crop-available-moisture, and precipitation is correlated with other climatic factors—temperature in particular.

Water (precipitation plus irrigation water) and temperature during the development periods of the corn crop were selected as the most crucial factors affecting yield. Preliminary statistical analysis, guided by previous research [5, 8, 12, 14, 16, 18, 19], indicated that the three 10-day periods prior to tasselling, the 10-day period including tasseling, and the two 10-day periods following tasseling were the periods showing the highest correlation between corn yield and water and temperature.

Elaborate methods of measuring moisture stress of corn have been developed [7, 21]. However, in this study simple transformations of water and temperature data were the explanatory variables used in the equation to estimate the yield response surface. Sufficient data to justify more sophisticated moisture stress measures were not available.

The production function to be used in the irrigation decision model contains other than climatic factors which are fixed at specified levels. These other factors, such as fertilizers and plant population, determine a separate production function in the climatic variables for each set of values that are specified for them. If one were to irrigate with a plentiful water supply, these auxiliary factors should be relatively high; conversely, as the irrigation water supply approaches zero, they should be at the optimum for dryland conditions. This study was conducted with the ancillary factors at a single set of values, since experimental data were not available for multiple levels.

The set of data used left much to be desired,

particularly with respect to the range of variation on water received. Only 122 observations were available and they were from unreplicated plots. Plant populations were 15,000 per acre and nitrogen application was 175 pounds per acre. A serious deficiency of the data was the absence of a record of occurrence of phenological events: emergence, tasseling, silking, and physiological maturity.

The following notation is used, with t denoting a particular 10-day period in the irrigation season:

v_t = precipitation;
u_t = irrigation water applied;
w_t = sum of irrigation water and precipitation truncated from below at .35 inch;
T_t = sum of daily maximum temperatures;
T_t^* = sum of the portion of daily maximum temperatures *exceeding* 85°F for all periods except $t=4$, and 90° for $t=4$;
T_t^{**} = sum of the portion of daily maximum temperatures *below* 85° and 90° for $t\neq 4$ and $t=4$, respectively;
$I_t = T_t^*\sqrt{\text{Max}(0,\ \omega_t - .35)}$ an interaction variable between water and high temperatures;
$t = 1, 2, \cdots 6.$

The purpose of truncating w_t was to discount the importance of extremely small amounts of precipitation during a given period. Temperature was divided into an upper and lower range in order to capture the obvious nonlinearity of its effects. Limited variation in the observed temperature values and the consequent high correlation between T_t and T_t^2 prohibited estimation of curvilinear effects through the use of a quadratic term in the model. Preliminary statistical analysis resulted in a better fit and more reasonable interpretation of temperature effects if the division of temperature was made at 90°F for the tasseling period and 85°F for all other periods.

The square root transformation of the water factor in the interaction term allowed diminishing returns to water within the interaction term and gave a better fit to the data. Effect here refers to the partial effect within a given 10-day period of a change in the water variable.

The equation fitted to corn yield is a form of (9) with linear terms added:

$$y = B_0 + B_1 U + B_2 U^2 + \sum_{t\neq 4} C_t T_t + C_4 T_4^* + C_4' T_4^{**} \tag{15}$$

where

$$U = \sum_{t=1}^{6} (a_t w_t + b_t w_t^2 + c_t I_t).^2 \tag{16}$$

A simplification of the above equation which deleted the first and last periods made only a trivial difference in the explanation of sample corn yields. Therefore, the model was simplified to include only four periods, i.e., periods for $t=2, 3, 4$, and 5 in equations (15) and (16). The estimated coefficients and other statistics of interest for the final model are presented in Table 1.

Table 1. Regression coefficients and other specified statistics for the estimated model

Coefficient	Associated variable	Estimate	Standard error
A. Weights or variables included in the composite variable			
a_2	w_2	7.9906	3.633
a_3	w_3	16.6982	3.138
a_4	w_4	− 4.3966	5.737
a_5	w_5	5.0473	7.368
b_2	w_2^2	− 0.0949	1.023
b_3	w_3^2	− 0.7414	0.450
b_4	w_4^2	0.8709	1.305
b_5	w_5^2	0.0757	0.248
c_2	I_2	− 0.1185	0.101
c_3	I_3	− 0.5991	0.046
c_4	I_4	1.2816	0.135
c_5	I_5	0.1384	0.067
B. Coefficients of the general polynomial			
B_0	—	−136.8968	—
B_1	U	170.6940	10.384
B_2	U^2	− 90.6738	8.933
C_2	T_2	.1449	0.037
C_3	T_3	.3458	.052
C_4'	T_4^{**}	.3674	.086
C_4	T_4^*	− 1.7531	0.101
C_5	T_5	− .5636	0.040

Standard error of the estimate: 9.40.
Coefficient of determination: 0.887.

Relatively satisfactory statistical reliability was obtained for parameter estimates in equation (15) (Table 1, part B), but the standard errors are quite large on parameter estimates of equation (16) (Table 1, part A). We did not resort to picking off separate parameters that were not significant at some arbitrary level but examined comprehensive changes in the algebraic form across all periods. The quadratic

[2] The set of parameters, $\{a_t, b_t, c_t\}$, are unique only up to a scalar multiple. Most statistical estimation procedures would require imposition of a constraint, such as the parameters summing to unity. However, the particular nonlinear least squares algorithm used by the authors was "custom built" for equations (15) and (16) and did not require such a constraint.

effects obtained by inclusion of b_2, b_3, b_4, and b_5 are justified only marginally on a statistical basis, but we chose to include them.

Estimation of a weather-yield response surface makes it possible to proceed with the task of determining optimal irrigation policies for corn. The final version of the yield response surface contains only four 10-day periods—the two periods prior to tasseling, the tasseling period, and the period after tasseling. Therefore, the intraseasonal decision process consists of five periods—the above four production periods plus a terminal or market period. The terminal period is an instantaneous end of the process rather than a time interval.

The empirical problem thus reduces to the model summarized by equation (13), $n=0, 1, \cdots 4$. Since the terms of equation (15) that explicitly involve temperature are additive, their expected values can be added to the constant term for purposes of the temporal allocation problem; therefore (15) reduces to

$$y = B_0' + B_1 U + B_2 U^2 \tag{17}$$

where

$$B_0' = B_0 + \sum_{t \neq 4} C_t E(T_t) + C_4 E(T_4^*) + C_4' E(T_4^{**}).$$

Since the first and sixth (last) periods have been deleted from the production function, U contains only four terms in the summation in (16) and the above summation of expected temperatures also deletes $t=1$ and $t=6$.

The general function of (9) for this special case is defined with

$$\begin{aligned} \phi_i(W_i) &= a_i w_i + b_i w_i^2 + c_i I_i \\ &= a_i(u_i + v_i) + b_i(u_i + v_i)^2 \\ &\quad + c_i T_i^* \sqrt{\operatorname{Max}(0, u_i + v_i - 0.35)} \end{aligned} \tag{18}$$

$$h(U) = B_0' + B_1 U + B_2 U^2, \tag{19}$$

and the function $\psi(Y)$ is suppressed. The vector of climatic variables in (9) is comprised of the three components u_i, v_i, and T_i^*.

We now define the periods of the irrigation season with respect to stages remaining in the decision process (see Figure 1); and (18) for stage n is defined as

$$Z^n = a_n w_n + b_n w_n^2 + c_n I_n, \quad n = 1, 2, 3, 4. \tag{20}$$

The recursion formula of (13) for this application is

$$\begin{aligned} f^1(s_1, s_2) &= \operatorname*{Max}_u \left[-c(u) + ER(B_0' + B_1(s_1 + Z^1) + B_2(s_1 + Z^1)^2)\right], \\ f^n(s_1, s_2) &= \operatorname*{Max}_u \left[-c(u) + Ef^{n-1}(s_1 + Z^n, s_2 - G(u))\right], \\ &\qquad n = 2, 3, 4. \end{aligned} \tag{21}$$

The maximization operation is subject to the constraints given in (13). The stochastic nature of the problem stems from the random variable Z^n which is a function of precipitation, temperature, and irrigation water applied in stage n. Recall that the function $R(\psi(Y)) = R(Y)$ in this application is gross value of the crop minus harvest costs.

There is great practical advantage in reducing the number of state variables in (21) to only one in order to obtain a numerical solution to the equations and an approximately optimal policy. In nonstochastic problems, a state variable can be eliminated by introduction of a Lagrange multiplier to represent an internal price for a resource [3, p. 52] such as stored water in this application. The transformation function associated with stored water, s_2, is nonstochastic, but the total model is stochastic. In this situation the Lagrange multiplier method of eliminating a state variable yields an approximately optimal policy, which should be quite close to optimal if properly interpreted.

Numerical solution also requires the remaining state variable, s_1, and the decision variable, u, to be approximated by discrete intervals on their continuous scales of measurement. These intervals on s_1 and u are denoted by $i=1, 2, \cdots M(n)$ and $k=1, 2, \cdots K$, respectively. The probability distribution for s_1+Z^n can be summarized by the finite set of probabilities:

$p_{ij}^k(n)$ = the probability that the process will occupy the jth state in stage $(n-1)$, given that it occupies the ith state in stage n and that the kth decision is made. The parenthetical n denotes that the probability of moving from one discrete level of the state variable to another changes from stage to stage.

With these modifications, the recurrence relation (21) can be approximated by

$$f^n(i) = \underset{k}{\mathrm{Max}}\left[-c(u_k) - \lambda G(u_k) + \sum_{j=1}^{M(n-1)} p_{ij}^k(n) f^{n-1}(j)\right] \tag{22}$$

where λ is the Lagrange multiplier, $M(n)$ is the number of states associated with the nth stage, and $f^0(j) = R(Y)$. The relation $f^n(i)$ corresponds to the earlier definition of $f^n(s_1, s_2)$ with i implying the ith discrete level of s_1 and the second state variable s_2 suppressed. The summation in the above expression corresponds to the expected value of $f^{n-1}(s_1+Z^n, s_2-G(u))$ in (21), but the second argument in f^n has been deleted by using the Lagrange multiplier on $G(u)$. The level of λ rations stored water, which eliminates the constraint $G(u) \leq s_2$.

Numerical solution of (22) is accomplished by computing the sequence $f^0(i)$, $f^1(i)$, $\cdots f^4(i)$, $i=1, 2, \cdots M(n)$; but of course, an electronic computer is required for a problem of much size. Many separate solutions are required for a range of values on λ, i.e., the recurrence relation in (22) could be more descriptively written as $f^n(i|\lambda)$. This procedure yields a series of solutions that are increasingly conserving of water as λ increases. That is, for each specified value of λ, there exists a corresponding policy and expected quantity of water used (available stock) under that policy. The one-to-one correspondence between policies associated with λ and expected quantities of water used (available stock) yields the answer to the question of how a limited stock of water should be allocated. The computational procedures of dynamic programming yield answers to this question at all stages and for all states of the sequential decision process.

The results obtained in solution of the problem introduce additional flexibility into selection of an approximately optimal policy which was not included in the original formulation of the problem. Results are available that make it possible to modify the derived policy at each stage as additional information becomes available. To illustrate, assume that a given quantity of water is available at the beginning of the decision process. The decision maker should select the derived policy for that stage as indicated by the value of λ which most nearly exhausts the quantity of water available (for the entire season in an expected value measure). Following this policy the decision maker will find his crop in some specified state one stage later when he again is confronted with selection of a policy that will maximize expected return. The stock of water available for allocation, as well as crop condition, may now be different from that anticipated, based on information available in the previous period. This difference could arise from rainfall resulting in runoff, equipment failures, sufficient precipitation to reduce the need for irrigation, or other factors such as unusual temperatures. The decision maker owes no allegiance to continuation of the policy indicated by the appropriate value of λ in the nth stage; he should follow a policy in the $(n-1)$ stage that will just exhaust (in an expected value sense) the stock of water presently available. Again, this selected policy will be associated with the value of λ which just exhausts the water in storage, given the state variable describing crop condition. The computational procedure yields results that allow for the selection of an approximately optimal policy stage by stage as new information becomes available.

The method of Lagrange multipliers applied to this problem yields policies that deviate from optimal insofar as the stochastic part of the process gives rise to changing marginal values of stored water among stages of the process. In a deterministic process marginal values would be equated among stages; but in a stochastic situation, only expected marginal values would be equal under an optimal policy. However, errors are greatly reduced by the above flexible interpretation of the decision rule. For a single-stage process, the method is optimal; for a two-stage process, error stems only from the random transition between the two stages, etc. The relatively short process involved in this application reduces the errors, and the generalized interpretation of the decision rules prevents compounding of the errors from stage to stage.

Empirical measures used

Transition probabilities $\{p_{ij}^k(n)\}$ were derived from a 74-year series of precipitation and temperature data collected at Columbia, Missouri, about 30 miles from the experimental site of the data. Since Z^n is implicitly a function of w_n and I_n which are in turn implicitly functions of u_k, it is more explicit to write Z_k^n for the discrete variable decision model. The probability distributions of Z_k^n were estimated by relative frequencies from the 74-year weather series. Since $k=1, 2, \cdots 5$ and $n=1, 2, 3, 4,$

twenty separate probability distributions were required. The five levels of net irrigation water application were 0, 1.6, 1.9, 2.2, and 2.5 inches for $k=1, 2, 3, 4, 5$, respectively. The number of discrete states in each stage, $M(n)$, are 48, 42, 23, 8, and 1 for $n=0, 1, 2, 3$, and 4, respectively.

One complication was encountered in computation of the transition probabilities. The 10-day periods are not fixed calendar periods but are related to the critical growth stage for corn, where tasseling date is taken as a base. This implies that the tasseling date of corn must be known for each year in the weather series before the probability distributions of the Z_k^n variables can be derived. Tasseling date was estimated for each year in the series using the method outlined by Stauber, Decker, and Zuber [20].

Items included in variable costs were fuel, oil, repairs, and labor. The computed costs per acre and related data are presented in Table 2 for selected rates (u_k). The variable costs per acre exhibit increasing costs per unit of water because of the decreasing soil infiltration rate of water per unit of time.

The function $R(Y)$, which defines gross returns from Y units of the crop per acre with harvest costs deducted, is simplified to \$.91Y, where 91 cents is the net price of corn per bushel and Y is in bushels. Production costs are assumed constant except for variable costs of water application and costs of harvest. The simplified relation $R(Y)=\$.91Y$ implies a cost of harvest proportional to yield which is merely a convenient approximation.

Empirical Results

Solution of the discrete model for the case where $\lambda=0$ is presented in Table 3. Solutions for other values of λ are similar but must be omitted because of space limitations. The case of $\lambda=0$ implies stored water is not an effective constraint at any point in the season. The optimal decision, expected returns per acre, and expected water use per acre are presented for all relevant stages and states. Expected returns per acre refer to the net market value of the crop minus variable irrigation costs. The greater λ (internal price of water), the more conserving of water is the optimal policy and the lower the expected returns per acre. Of course, the internal pricing of water through λ is not reflected in the expected returns measure presented.

The general pattern of optimal policies for λ greater than zero is much the same as that in Table 3. At higher values, progressively smaller

[a] Net returns are equal to net market value of the corn crop minus variable irrigation costs. Corn valued at a net market price of 91 cents per bushel.

and smaller applications of water are made at a given stage and state; also applications are made at fewer states. Interpretation of the optimal policy for any value of λ is straightforward. At each stage and for any state defined for that stage, the appropriate decision, expected return, and expected amount of water needed to implement the optimal policy through the present and subsequent stages of the season are presented.

The results define optimal policies for all stages and states under all meaningful levels of water availability. The results for stage four are particularly interesting as they provide information that is useful in an organizational as well as an operational sense. The expected returns for stage four comprise the annual expected net market value of the crop minus variable irrigation costs. Deduction of other production costs and appropriate overhead costs would allow evaluation of the profitability of irrigated corn production.

One surprising result is that no irrigation water is ever applied during stage three, the period before tasseling. An apparent explanation is the discrete nature of the irrigation variable combined with a production function that makes overirrigation a possibility. The quadratic function in the composite variable U definitely permits negative effects from too much water. Sequencing of the discrete levels of irrigation permitted, and the stochastic environment, could easily give a decision rule that delayed irrigation from the third stage to the second. Also, the heavy irrigation in stage four may partially substitute for irrigation in stage three.

Variability of returns as an additional criterion

Variance of returns is an important economic consideration in making the decision to adopt a production or management practice. It seems logical that some control over a random production input such as water would result in reduced variability of returns as well as greater expected returns. The properties of Markov chain transition probability matrices can be exploited to determine the variability of returns for a specified policy. It is possible to find the probability that the process occupies each of its states after moving through a number of stages by post-multiplying the initial-state probability vector by the product of the appropriate transition matrices [15, p. 218]. Specifically, for the model used in this study, let

$P_n =$ the transition probability matrix for stage n under an optimal policy;
$n = 1, 2, 3, 4.$

A specified policy designates a decision, k, to be associated with a given state, i, and stage, n, thereby defining a unique transition matrix for each stage. The elements of the matrix P_n are a subset of the $\{P_{ij}^k(n)\}$.

A terminal-state probability vector, say π, can be computed by evaluation of the following expression:

$$\underset{(1\times 48)}{\pi} = \underset{(1\times 8)}{P_4} \cdot \underset{(8\times 23)}{P_3} \cdot \underset{(23\times 42)}{P_2} \cdot \underset{(42\times 48)}{P_1}$$

Terminal-state probability vectors for an

optimal policy under unconstrained water availability and for dryland conditions are presented in Table 4 to illustrate the nature of the distributions.

The terminal-state probability vectors along with the associated values of gross returns for each terminal-state constitute the probability distribution of gross returns and allow the computation of the expected value of gross returns and variance of gross returns for each optimal policy. Variance of gross returns is a very close approximation to the variance of net returns. They would be identical if production and water costs were the same for all states.

The terminal-state probability vectors and associated values of gross returns were used to compute expected value and variance of gross returns for selected values of λ. The data are presented in Table 5 and indicate a clear superiority with respect to variance of returns for the policies involving intensive water use. The variability of returns (measured by the standard deviation) for the "unconstrained water availability" case is approximately one-half that of the dryland situation pointing out the twofold benefits provided by irrigation.

Table 4. Value of the state variable, associated corn yield, and probability of occurrence under an optimal policy with unconstrained water availability and for dryland conditions

Value of the state variable[a]	Yield per acre	Probability of occurrence: Unconstrained water availability	Probability of occurrence: Dryland

10.0	105.1	95.24	26.05	.272
Dryland	102.5	93.24	29.67	.318

[a] Gross returns are equal to the net market value of the corn crop valued at a net market price of 91 cents per bushel.

Actually, the data in Table 5 overstate the benefits of intensive levels of water use. These data provide the basis for an analysis using the joint criteria of mean and variance of returns, but the expected gross returns values would need to be adjusted by subtracting amortized fixed costs of investments to provide and apply irrigation water. The joint-criteria decision models tacitly assume a sacrifice in one criterion to gain in the other, at least within the relevant region for decision making [4, 11, 17]. This would require a direct relationship between the mean and variance of returns in the relevant decision space. The unadjusted data reflect an inverse relationship between mean and variance of returns.

Adjustment of expected gross returns by subtraction of amortized fixed investment costs for each value of λ would probably result in an expected return function that is unimodal in the variable λ and reaches its maximum where $\lambda > 0$. This maximum would result from the rapidly increasing levels of investment necessary in most farm situations to achieve the intensive levels of water-use reflected by small

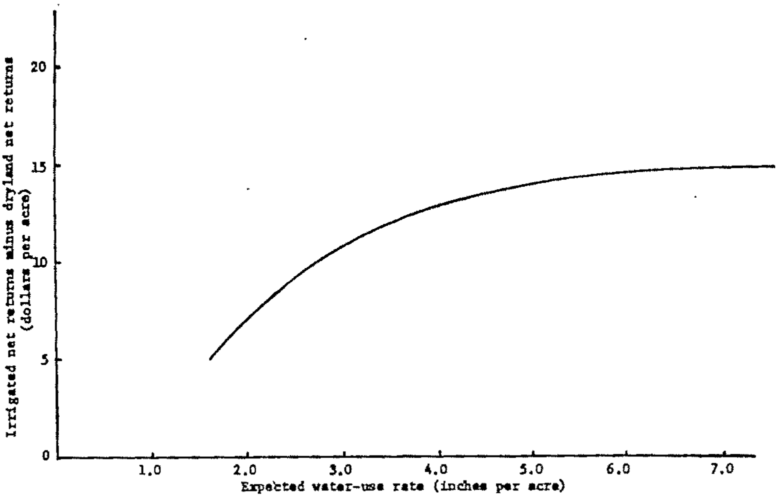

Figure 2. Relationship between water-use rates and the per acre differential in irrigated net returns and dryland net returns.

lambda values. If this were the case, the decision maker would be confronted with the choice of how much expected income to sacrifice for reduced variability in income, or vice versa.

Application of results to the investment decision

The temporal allocation model used water in storage per irrigable acre as a state variable, which tacitly requires all acres to receive the same irrigation treatment. The investment decision framework presented at the beginning of the paper is now applied to this simplified situation. This application further assumes that there is an ancillary relation dictated largely by engineering considerations that specifies y as a function of x and z for any on-farm situation. Therefore, the quasi-rent function is reduced to simply $N_t(x, z)$ for a given farm situation.

The initial cost of investment function, $I(x, y, z)$, is also simplified by the above assumption about distribution capacity and is redefined without the argument y as $I(x, z)$. This function is viewed as that associated with a particular farm situation with given physical conditions for building storage reservoirs and developing irrigable land. Replacement and maintenance costs that are implied by an initial investment of $I(x, z)$ are reflected in the future quasi-rents, $N_t(x, z)$.

We need the counterpart of $\bar{g}(x, y, z)$, given by equation (14b), with the argument y suppressed; we denote that function by $\bar{g}(x, z)$. Likewise, the second argument of $g(s_2, D)$ in equation (14) is suppressed, giving the simplified function $g(s_2)$. Recall that s_2 is water in storage per acre at the beginning of the season and $g(s_2)$ is expected net returns per acre following an optimal irrigation policy. The approximating device of the Lagrange multiplier used in the application yields a function comparable to $g(s_2)$ except that the argument is expected water used per acre irrigated under an optimal policy. This latter function is used to approximate $g(s_2)$, and equations (14a) and (14b) provide the means for obtaining $\bar{g}(x, z)$. The function used to approximate $g(s_2)$ is graphed in Figure 2. The graph has been scaled as a differential above dryland expected returns, which merely forces $g(s_2)$ through the origin instead of it having a positive intercept.

Any analysis from this point would be specific to some farm irrigation site, and the function $\bar{g}(x, y)$ would have to be estimated for the particular farm for which investment in irrigation is being considered.

The Team Approach and Extension Economics

KEN D. DUFT

With the introduction of new Extension programs in such nontraditional areas as recreation, community resource development, environmental quality, etc., Extension economists will experience some loss of professional autonomy. Rarely will the resources required by these programs be found within the agricultural economics profession alone. This paper proposes that Extension economists adapt the team approach to their contemporary programs. More specifically, the Program Mission Organization is suggested as the interdisciplinary form of organization most applicable. The benefits and limitations of the team approach are then examined in light of a need for operational efficiency within and between all Extension economics programs.

IN THE Snake River Canyon of northern Idaho can be found ancient Indian pictographs showing a hunter chasing his game in the direction of his hidden companions to facilitate the kill. These drawings stand as evidence that the team approach to one's pursuits is hardly a new concept. Perhaps the greatest testimonial in favor of the team approach is that it has not only endured over the ages but has permeated so many aspects of our lives. Its relevance to programs in Extension economics is now being illustrated [2, 6].

Extension agricultural economists are rarely blessed with work patterns of predetermined origin. Their efforts are directed towards so-called "real world problems," the solutions to which are rarely found within the agricultural economics profession alone. Extension economists are often not allowed the luxury of selecting and pursuing a specific phase of a broad problem; instead, they must consider the whole problem and assemble that talent (even from outside our profession) needed to achieve an ultimate solution. As a result, the work of Extension economists often appears in the form of a contribution to a team effort. The team, itself, may be interdisciplinary or intradisciplinary in nature. Regardless, within the context of a team approach, the pursuit of an individually preselected subject matter becomes difficult, if not impossible. One no longer functions as an agricultural economist. Instead, his talents are meshed with those of other scientists to form a broad resource base from which talents are drawn according to the need rather than according to personal preferences.

Hence the team approach to the conduct of programs in Extension economics has considerable appeal, and I propose that the team approach should become a dominant feature of Extension programs. If this is to be achieved, however, numerous operational problems inherent in the team concept itself must first be overcome. Furthermore, other problems concomitant with the team approach (e.g., coordination, the natural human desire for professional autonomy, and psuedo-commitment) have not been adequately considered.

In support of my proposal, the objectives of this paper are four-fold: (a) to define the team approach and describe its three alternative conceptualizations; (b) to discuss the adaptability of the team approach to Extension as a formal organization; (c) to elaborate on the benefits and limitations of the team approach as they apply to agricultural economics Extension; and (b) to discuss other operational problems inherent in the administration of Extension economics programs based on the team concept and offer some potential solutions.

Definition

The team approach is commonly defined as a singular all-encompassing phenomenon whereby "two or more persons commit themselves to a series of systematic actions" [2, p. 83]. Students of management have dissected and categorized the team approach into a more definitive and workable multiplicity.

Wickesburg and Cronin [9], in establishing a team concept, called it a Task Force (a term first used in the U. S. Navy), that is a team of persons under singular command, devoted to the accomplishment of a specific objective or mission. Members of a task force are drawn mainly from within the organization and are selected for their potential contribution to the successful attainment of the mission. Once the task has been accomplished, they are returned to their original organizational units. The task force itself therefore enjoys only a temporary existence in the organization's total life span.

KEN D. DUFT is extension marketing economist and assistant agricultural economist at Washington State University.

In 1967, Reeves suggested that "if a task force is to be effective it must have considerable autonomy within the area of responsibility assigned to it "[7, p. 75]. The granting of such autonomous authority requires that the organization have such clearly defined areas of responsibility that managerial control is not sacrificed. Unfortunately, as will be discussed later, enucleated bureaucracies such as Extension find it difficult to establish clearly defined procedures and lines of responsibility. The task force form of the team approach therefore is rarely appropriate in Extension.

The team approach is followed by some multifunctional organizations; e.g., construction firms often subcontract several functional activities such as electrical, plumbing, and masonry work. But the task force concept is rarely applicable to this type of multifunctional activity because its application requires the forfeit of many multifunctional attributes. The Matrix Organization concept of the team approach then was developed by William G. Scott [8] who described the organizational and procedural relationships that emerge when an organization applies the team approach across functional lines. Scott's perception of the resultant matrix shows the various teams (each having a nonfunctional orientation) listed on the vertical axis and the organizations's functions listed across the horizontal axis. Cross-representation (i.e., a team member in each function or a functionary on each team) is mandatory. As a result, the matrix organization must be conceptualized as a total system that is constructed to achieve maximum team-function coordination. It proves most practical, therefore, when applied to organizations concerned with a large number of relatively small projects, each requiring a homogeneous mix of functional talents. Rarely is this characteristic of our modern-day Extension activities with their problem, not functional, orientation.

Finally, Johnson, Kast, and Rosenzweig [4] defined a third team concept called the Program Mission Organization (P.M.O.). Under P.M.O. each task assigned to a team was related to a mission. Each mission was dependent on (a) perceiving a need, (b) designing a successful program, (c) stimulating a demand for the program, (d) conducting the program effectively, (e) distributing relevant information, and (f) educating potential program users. This team concept has proven most beneficial to organizations that are composed of a variety of programs ranging in size, scope, complexity, and duration. The six-point mission criterion forms the basis for some degree of uniformity, continuity, and cohesiveness among the program teams.

Of the three concepts of the team approach, P.M.O. seems most consistent with the composition of most Extension economics programs.

Composition

A team must not be confused with a committee; it is granted a different scope of authority and responsibility. For example, a team is rarely created to act as a judiciary body, nor is it primarily an educational or training body. A team is assigned a mission; it has a leader and often a mandatory completion date. Rarely is a team in a position to "pass the buck," postpone a conclusion, or file a minority report. While a committee is normally asked to conduct an investigation and report its findings to a governing body, a team is established to take positive action in response to its findings and is given the authority to do so. The performance of a team, unlike that of a committee, is often rather abrupt; e.g., it either succeeds or fails.

The team, therefore, is an action-oriented group of individuals. Team membership is not based on the fact that the assigned topic may simply "be of interest" to an individual nor that all political factions or academic departments "must have a representative spokesman." Unlike a committee, a team may range from an informal temporary assortment of persons constituted to attack a minor short-lived problem to a highly sophisticated assembly of specialists designed to ponder more dynamic and expansive difficulties. In the former, the team member may maintain his administrative ties and normal responsibilities with his own department or discipline; in the latter, all such ties may be severed for a designated period of time during which full-time efforts are team-directed.

Most authors choose not to describe where, between these two extremes, their envisioned teams would lie. Yet, between these two extremes exists an infinite number of task-related team compositions, each requiring a unique organizational structure. I shall mention only four possibilities:

(1) Team members remain in their functional or departmental location and area of supervision, but work related to the team effort takes priority over functional or departmental work.

(2) Team members remain in their functional or departmental location but are officially assigned to the team leader for work scheduling and related administrative purposes.
(3) Team members are located temporarily away from their normal employment location and are grouped with other team members in an area specifically assigned to their program.
(4) Team members are located physically outside the delegating agency and under the authority of the team leader for the duration of the program.

Extension economists are familiar with these and other location-function-administrative combinations; e.g., their activities are often supervised by some combination of administrators from both Extension and the academic department.

Adaptability

According to Becker and Gordon's taxonomy of formal organizations [1], Extension could be described as an enucleated bureaucracy [1, p. 329], i.e., an organization in which the administrator (institution) stores the specific resources (scientists) necessary for goal achievement (problem solution) but finds it difficult to specify the procedures for their coordination because of complex environmental interaction and the need for rapid response to problems [1, pp. 324 and 333]. These authors define a "specific resource" as one stored by the organization in the form necessary to implement a program with the administrator's intent that it be used; and "procedures specified" as administrative requirements that a volitional resource perform a planned activity in the attainment of the goal [1, pp. 322–323].

Under such an organization, the employees generally specify their own work procedures, and self-coordination soon replaces the need for large amounts of direct administrative control. This is the type of academic freedom enjoyed and preferred by most Extension economists. It results in uses of resources as sanctioned through consensus among Extension economists rather than by administrative directive. An enucleated bureaucracy's authority pattern appears as a system of control in which some authority is shared by all members of the working group (team). Not only does this classification typlify Extension; it also describes a campus organization particularly well suited to the adoption of the team approach, i.e., both the organization and the approach imply an administrative pattern whereby ".... much authority is deemed to rest in groups of people (teams) rather than in an individual (an administrator)" [5].

The team approach, therefore, is easily adopted by an enucleated bureaucracy such as Extension. In fact, when it is adopted, the resultant organization is described by Becker and Gordon as an internally coupled enucleated bureaucracy [1, p. 325].

Benefits

Mankind has long been aware of the many favorable attributes of the team approach. The following benefits are most often acknowledged:
(1) By virtue of its multispecialist composition, a team is better able to cross organizational lines and shortcut time-consuming conventions in an attempt to move rapidly on a problem.
(2) Diverse professional skills and experience are assembled to facilitate the solution of problems requiring expertise beyond a single discipline or academic department.
(3) By encouraging participation of specialists from many functional groups, the team approach discourages empire-building by dominant individuals, departments, or agencies.

Other equally well-recognized benefits of the team approach could be listed. Two of these are directly attributable to Extension economics programs and deserve special mention.

First, the team approach better equips an organization to cope with a rapidly growing need for interpersonal communication. Extension economics programs are characterized by large numbers of different communicating factions, e.g., Extension (including county, area, and state level personnel), the department of agricultural economics, other academic departments, numerous public agencies, and, of course, the audience (which may include farmers, merchants, bankers, etc). The magnitude of this growing communication problem is cause for concern.

Second, Extension economics programs are now being conducted within a complex political system. Each subsystem (public agency, institution, political interest group, etc.) added to the programs of Extension economists increases administrative complexity geometrically, not linearly. The team approach appeals to one's democratic principles and desire for the consideration of opposing views. While each con-

cerned subsystem may not have a "representative" on the team, each is better assured of having its position recognized.

Duration, Fluidity, and Flexibility

The application of the team approach to Extension economics does not establish a fail-safe system. In fact, its application is laden with numerous limitations which must be acknowledged before any degree of success can be achieved. Some limitations result from the characteristic of all organizational structures—their tendency to become rigid and perpetual. Others are related to supervision and evaluation of the human contribution to the team effort. Finally, a series of operational questions may evolve which, if left unanswered, could greatly reduce the effectiveness of the team approach. These limitations and problems are discussed below, together with relevant guidelines and solutions.

An implied reference to a "team" denotes a working body with an independent operational status and an ability to transcend usual functional (and perhaps departmental) lines. However, little or no reference is generally made to the operational status of such a working body.

To prove ultimately successful, membership on a team must be fluid; i.e., new personnel are assigned to the team as needed, and others, upon completion of their particular function, return to their particular functional or departmental posts [9, p. 113]. This is not to imply that an Extension economist must necessarily drop his normal duties and work full time for the team until completion of its task or his contribution. It isn't an either/or situation. Both the agricultural economist's conventional tasks and his team effort may be carried out simultaneously. A team should be able to add new members when their potential contribution is high and drop them when their specific contributions have been made and there is no immediate need of their talents. Fluidity in team membership, therefore, allows the team to adjust rapidly to changing demands and requirements. Despite its fluidity, however, the team remains a viable unit for the duration of its task.

Many Extension economists fail to recognize the necessity of having a clearly defined end point when participating in a team project. Failure to establish an end point may result in an undefinable team duration wherein the team becomes a permanent part of the overall organization and struggles for its life long after it is no longer worth saving. This is not to exclude the possibility of a highly proficient team being assigned to successive projects, thereby extending its active duration.

Unfortunately, Extension is particularly susceptible to the "sins of immobility"; i.e., teams are established within Extension, membership tends to remain rigid, and professional dialogue is soon "burned out." The teams then fabricate problems (and programs) to assure their continued existence beyond their productive lives. To avoid this, administrators should perhaps delegate to a team the responsibility of attaining a "satisfactory" rather than a "perfect" solution to a problem. Differentiation between the two is, in large part, an area of judgment which is impossible until at least one solution appears. Nevertheless, such a designation is more indicative of a recognizable end point with definitive parameters within which the solution should fall and team life ended.

Finally, the team approach places primary emphasis on the mission or objective. Because of this mission orientation, the team members become a semi-selfsufficient entity within the general confines of the parent organization. Thorough understanding of the nature of its mission gives the multidisciplinary team a decided advantage over its more traditional divisional or departmental counterpart in that simultaneous efforts on more than one aspect of a broad problem are facilitated and phasing from one state of development to the next is made more easily. The latter results in part from the continuous indoctrination about project progress received by team members. There is no time wasted getting a "feel" of the project or exploring avenues of earlier investigation which happens with the interdepartmental approach. In short, the loss of this mission orientation is likely to result in a substantial reduction in the degree of flexibility inherent in the team approach [9 p. 114].

Supervision and Evaluation

Cosgriffe and Dailey were keenly aware of the critical importance of team supervision and evaluation [2, pp. 84–85]. They acknowledged that the team leader must display an ability to identify and measure membership commitment; further, an important part of their proposal is that the team leader should observe team members' choices of action and sanction those that support team effort.

Experience has shown, however, that when

the team approach is applied to Extension economics programs, obstructions appear with alarming frequency. First, it is likely that each team member finds himself under two administrative heads, i.e., his departmental or Extension supervisor and the team leader. This violates the unity-of-command principle and creates obvious administrative dilemmas. Second, the scalar principle is no longer applicable because the team does not lend itself to hierarchical concepts [4, p. 146]; i.e., team leaders and department or Extension administrators, while organizationally distinct, do not appear in an explicit scalar relationship. Finally, the meaningful line-staff relationships between the team and the rest of the organization have a tendency to disappear [9, p. 113].

The breakdown of these three administrative principles complicates the work of the team and an evaluation of its performance. Scott goes so far as to say that the developing scalar indeterminancy between team leaders and departmental administrators, ". . . . gives rise to a transactional climate where bargaining and compromise are common in resolving conflicts over the allocation of personnel and performance appraisal" [8, p. 132].

Supervision and evaluation under the team approach thus becomes more difficult. To cope with this increased difficulty, one may consider the use of a system of saturation measurement (similar to that used in many commercial bank audits). Instead of periodic supervisory measurement, a series of random team audits by specialists and colleagues outside the team is conducted. Using Cosgriffe and Dailey's observation criteria, the evaluators could then measure team progress and efficiency of resource use, an ability greatly needed by Extension administrators. This method of evaluation could be expected to reduce intrateam conflict and the destructive influence of Scott's administrative "bargaining" noted earlier. Such a random audit evaluation system would also serve to assure team leaders that team performance is being observed and enable them to communicate to their team members the importance of establishing short- and long-term goals against which progress could be more easily measured. Team leaders themselves would be encouraged to incorporate into team project proposals some schedule showing intermediate progress points and definitive endpoint criteria, thereby blocking a meaningless prolongation of the team.

Other Problems

If teamwork is to become a major component of Extension economics programs, it will require changes at all levels of program supervision, planning, and conduct. Large-scale changes in any organization involve at least two operational problems: (a) structural resistance, i.e., a reluctance to change the line of command, administrative scope, etc.; and (b) human resistance [10, p. 686]. While the first appears only in the early stages of the introduction of change, the latter is longer lasting, occurs at all levels of the organization, and is quite often found in its most advanced form among the very administrators whose cooperation is essential. In this regard, one must recognize that the human problem in introducing change often exists not as an objection to the goal but rather in the perceived probability of its attainment. A second reason for human resistance is the vulnerability of one's professional position relative to the success or failure of the change. The human side of the required change in Extension economics programs can create a severe test of an administrator's understanding of communication and motivation. He must not only hear what is being said; he must also be able to understand why it is being said. His response is conditioned both by his own perception of the change and by his understanding of others' perception of it.

The team approach, when applied to Extension economics programs, also produces a number of not readily answerable questions:

(1) Where will the team members come from? Unless an individual is a "standby reservist," that is, unless he is essentially excess personnel pending a team assignment, he must be assigned some activity that can be economically justified. Extension cannot afford any excess fat in its personnel complement and has no excess positions available for the staffing of teams. Hence the individual's major Extension assignment is likely to suffer while he is serving on a team either from the lack of a replacement or from one with insufficient background and knowledge.

(2) Once a project has been completed or a team member's contribution is ended, how effectively will he return to his original assignment? Productivity is likely to be lost as the person switches back and forth.

(3) Can faculty positions and assignments be flexible enough that the academic department

will have available a pool of qualified team members?

(4) Can academic criteria for advancement be made sufficiently comprehensive and flexible to reward an individual equally for Extension service and the often more highly regarded categories of teaching and research?

The team approach may also create some unusual problems for supporting agencies. The financial office, for example, is soon confronted with more complicated funding and allocation requirements. First, periodicity loses its validity in communicating with finance officers when either the project or the team's life span may be in terms of days, months, or years. This indeterminate life span of a team and the lack of necessary fiscal information (cost and allocation standards) provides no control points such as those existing in the periodic closing of normal organizational records and accounts. Second, existing fiscal expense classification systems based upon natural functional or departmental lines require some modification when authority is diverted to the team level. Finally, recognition of team productivity (and resource deficiencies) may also become apparent only upon the dissolution of the team. During the active life of the team, therefore, finance officers are apt to fail to see the relevancy of set objectives, alternative strategies, and their financial support requirements [3, pp. 111—121].

Conclusion

If our administrative soothsayers are correct, during the next ten years Extension economists will find themselves involved with programs vastly different from today's [6, pp. 13–16]. For example, problems related to recreation, community resource development, environmental quality, and other socioeconomic elements will be of vital concern to the Extension Service. In only a few agriculturally-related Extension programs will agricultural economists be able to retain a degree of professional autonomy. When in search of solutions to those broader social and economic problems, Extension economists will find it not only desirable, but mandatory, to seek advice and assistance from other professional disciplines. Professional identity will be lost as the team approach to problem solution becomes a more dominant feature of Extension's efforts. Each team (or P.M.O.), for example, will be mission-oriented and multidisciplinary in composition.

This paper supports the application of the team approach to Extension economics programs. To facilitate its adoption, an efficient system of personnel transfer from academic department to Extension team (and vise versa) should be established. Each team should (a) be able to add to or subtract from its membership in response to an existing need, (b) operate toward clearly defined end points in both time and accomplishment, and (c) adopt a system of saturation measurement for performance evaluation.

The benefits derived from the team approach will enable agricultural economists to participate more effectively in those Extension programs requiring contributions from numerous professional disciplines. The most notable benefits will appear in the form of an improved ability to deal with (1) the complex political system within which Extension now exists and (2) the greater need for interpersonal communications between and among Extension personnel and the people they serve.

A Linear Alternative to Quadratic and Semivariance Programming for Farm Planning Under Uncertainty*

P. B. R. HAZELL

Quadratic decision criteria for farm planning are theoretically appealing but difficult to handle computationally. This paper reviews the advantages of the quadratic approach and develops a linear alternative which, while retaining most of the desired features of the quadratic models, can be readily solved on conventional linear programming codes with the parametric option.

LINEAR PROGRAMMING is widely recognized as a method for determining a profit maximizing combination of farm enterprises that is feasible with respect to linear fixed farm constraints. The conventional deterministic model ignores uncertainty,[1] however, and may lead to a farm plan that is unacceptable to a farm operator on the basis of previous experience. Uncertainty may arise in the linear programming model in forecasted costs, yields, and prices for individual activities; in activity requirements for fixed resources; and in the total fixed constraint levels.

This paper is concerned with uncertainties in activity costs, yields, and prices that affect the objective function of the conventional linear programming model. They may be summarized usefully as uncertainties in gross margins (gross returns net of variable costs). Quadratic programming, as developed by Markowitz [14, 15] for portfolio analysis, has been suggested as a useful method to consider gross margin uncertainty in farm planning [3, 10, 12, 16, 20]. But application of the technique depends on access to a special computer code of which there are few in existence with the desired features and capacity.

The quadratic programming model is reviewed in this paper and desired features of its expected income-variance criterion considered. Recognizing that quadratic programming must frequently be performed on time series or cross-sectional sample data, an alternative expected income-mean absolute deviation criterion is proposed. This criterion leads to a linear model that can be solved by parametric linear programming yet retains many of the desired features of the expected income-variance criterion. Conditions for a direct relationship between the variance and mean absolute income deviation are also discussed, in which the mean absolute income deviation can actually be viewed as a reasonable substitute for the variance in developing efficient income-variance farm plans. Finally, the properties of the expected income-mean absolute deviation criterion are explored as it relates to Markowitz's semivariance model [15].

Quadratic Programming

The expected income-variance ($E-V$) criterion of quadratic programming assumes that a farmer holds preferences among alternative farm plans solely on the basis of their expected income E and associated income variance V. This will be true if the farmer has an E-V utility function [15]. Quadratic programming further assumes that the iso-utility curves are convex, or that the farmer is a risk averter (Figure 1). That is, along every iso-utility curve $\partial E/\partial V>0$ (the farmer would prefer a strategy with higher V only if E were also greater) and $\partial E^2/\partial V^2>0$ (this compensation must increase at an increasing rate with increases in V). Markowitz [15] has shown that it is sufficient for the farmer's von Neuman and Morgenstern [22] utility-of-income function to be quadratic and convex down for this condition to hold. Tobin [21] has established more general conditions, but these hold only when income distributions are normally distributed [5].

Given these assumptions, a farmer rationally should restrict his choice among those farm plans for which the associated income variances are minimum for the given expected income levels. The purpose of quadratic programming is to develop the set of feasible farm plans having the property that variance V is minimum for associated expected income level E. Such plans are called efficient E-V pairs and

* The author is greatly indebted to R. B. How, Timothy D. Mount, and Mark J. Eisner for their enthusiastic assistance in developing this paper.

[1] Uncertainty is used in this paper to denote situations in which knowledge of future events is limited to estimates of both possible outcomes and relative frequencies.

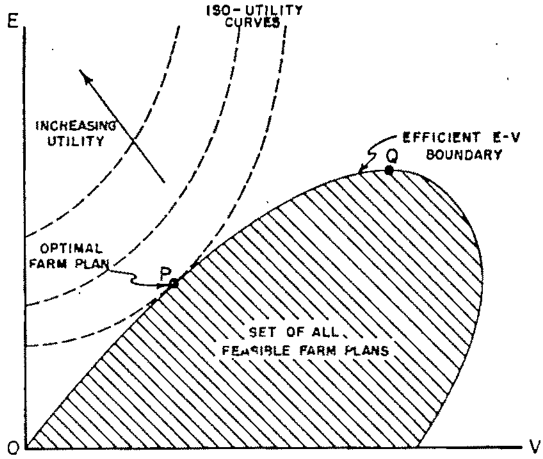

Figure 1. The optimal *E-V* farm plan

define an efficient boundary over the set of all feasible farm plans (segment OQ in Figure 1).

Since short-run planning models assume farm overhead costs to be constant for the length of the planning horizon, the income distribution of a farm plan is totally specified by the total gross margin distribution. The quadratic programming model can therefore be defined as follows in terms of activity gross margins:

$$\text{(1)} \qquad \text{Minimize } V = \sum_{j=1}^{n} \sum_{k=1}^{n} x_j x_k \sigma_{jk}$$

such that

$$\text{(2)} \qquad \sum_{j=1}^{n} f_j x_j = \lambda \qquad (\lambda = 0 \text{ to unbounded})$$

and

$$\text{(3)} \qquad \sum_{j=1}^{n} a_{ij} x_j \leq b_i \qquad (\text{for all } i, i = 1 \text{ to } m)$$

$$\text{(4)} \qquad x_j \geq 0 \qquad (\text{for all } j, j = 1 \text{ to } n)$$

where

x_j = the level of the jth activity;
f_j = the expected (forecasted) gross margin of the jth activity;
σ_{jk} = the covariance of gross margins between the jth and kth activity when $j=k$ and the variance coefficient of gross margins for the jth activity when $j \neq k$;
a_{ij} = the technical requirements of the jth activity for the ith resource or constraint;
b_i = the ith constraint level;
n = the number of activities;
m = the number of constraints;
λ = a scalar.

The sum $\sum^n_{j=1} f_j x_j$ is the expected total gross margin E, and $\sum^n_{j=1} \sum^n_{k=1} x_j x_k \sigma_{jk}$ is the expected variance V. By parameterizing λ from zero to unbounded, a sequence of solutions are obtained of increasing total gross margin and variance until the maximum possible total gross margin under the resource constraints has been attained.[2] Solutions are obtained for critical turning points in the solution basis, such that for the current total gross margin E, determined by λ, the variance V is minimum. These solutions are sufficient to define the efficient E-V boundary since efficient E-V plans for intermediate levels of E can be derived by linear interpolation on adjacent turning point solutions.

Given a set of efficient farm plans the acceptability of any particular one to an individual farmer will depend on his preferences among various expected income and associated variance levels as described by his E-V utility function. When this function can be measured, a unique farm plan can be rigorously identified which offers the farmer highest utility [13, 15]. This is the efficient farm plan P in Figure 1. However, since progress toward the specification of such utility functions is apparently slow, the better alternative for the immediate future seems to lie in obtaining the set of efficient farm plans and allowing the farmer to make the final choice. This approach is also more flexible in avoiding too rigid a specification of the utility function and perhaps compensates to some extent for situations where income variance is not the best measure of uncertainty. Further, if other socioeconomic factors enter the utility function in addition to E and V, the farmer is free to choose the plan he most prefers in relation to a multiplicity of goals.

Data Requirements of Quadratic Programming

The quadratic programming model (1)–(4) requires knowing a priori the mean gross margins for each activity (f_j; $j=1$ to n) and the corresponding variances and covariances

[2] The solution for maximum λ is actually the linear program solution for the forecasted gross margins. For a geometric analysis of these relationships see How and Hazell [12].

(σ_{jk}; j, $k=1$ to n). As these parameters are unknown, it is necessary to obtain estimates using time series or cross-sectional data of observed gross margins. Under certain circumstances subjective parameter values may be available from the farm operator, and farm operators may prefer to accept plans derived from their own subjective parameter values. However, this type of information is very difficult to obtain for a complex farm business, and it is unlikely that all variance-covariance parameters are specified. A practical compromise is to use estimated values at the outset but to make adjustments, if necessary, with available subjective information.

Regardless of the estimation procedure, estimated means and variance-covariance coefficients are generally regarded as nonstochastic parameters in the quadratic programming model, even though statistical properties of the estimates may be known.[3] This consideration is rarely discussed in quadratic programming studies, but estimated coefficients are implicitly assumed to be either subjective or nonstochastic parameters. Unless the original sample estimates are adjusted or confirmed by farmer expectations, however, such assumptions are not strictly valid.

To illustrate the standard estimation procedure, the variance V in equation (1) is replaced by

$$(5)\qquad \sum_{j=1}^{n}\sum_{k=1}^{n} x_j x_k \left[\frac{1}{s-1}\sum_{h=1}^{s}(c_{hj}-g_j)(c_{hk}-g_k)\right]$$

where $h=1$ to s denote s observations in a random sample of gross margins, and g_j is the sample mean, $1/s\ \sum_{h=1}^{s} c_{hj}$, of the gross margins for the jth activity, ($j=1$ to n) which may differ from the forecasted value f_j if subjective information is incorporated for these values.[4] Taking the summation over h to the left and factoring, the estimated variance is

$$(6)\qquad \frac{1}{s-1}\sum_{h=1}^{s}\left[\sum_{j=1}^{n} c_{hj}x_j - \sum_{j=1}^{n} g_j x_j\right]^2$$

Now $\sum_{j=1}^{n} c_{hj}x_j$ is the total gross margin of a particular farm plan evaluated with observed gross margins for the hth sample observations, and $\sum_{j=1}^{n} g_j x_j$ is the total gross margin for the same farm plan evaluated with sample mean gross margins. Income variance can therefore be calculated with sample data either indirectly from the individual activity gross margin distributions, equation (5), or directly from the total gross margin distribution, equation (6). Thus, when subjective expectations are at most available for the forecasted gross margins, equation (6) can be substituted as an estimate of equation (1) in the quadratic programming model.

Covariance relationships (particularly when negative) are fundamental for effective diversification among farm enterprises as a means of hedging against uncertainty [9]. However, when using the estimation procedure defined in equation (5) and hence (6), it is readily seen that the covariance relationships depend upon the patterns of interrelationships captured between the sample set of mutually exclusive vectors of possible activity gross margin outcomes together with their relative frequencies of occurrence. In other words, when defined on sample data the quadratic programming model recognizes gross margin interrelationships by recognizing the mutually exclusive nature of the sample gross margin vectors. This means that linear combinations of the sample vectors are ruled out so that sets of gross margin outcomes are not anticipated in the solution procedure that are worse or better than any individual sample vector. But many other measures of income dispersion exist besides the variance which are capable of using this same information and which lead to efficient two-parameter models [8].

Advantages of the *E-V* Criterion

The *E-V* criterion is particularly attractive for farm management research for the following reasons:

(a) The criterion is consistent with probability statements with respect to the likelihood of occurrence of different income levels for a given farm plan [18]. If total gross margins can be expected to be approximately normally distributed,[5] and if the variance-covariance

[3] This is analogous to the widespread recommendation of optimal input levels from statistically estimated production functions without regard to the sampling distribution of such estimates.

[4] This, because the forecasted gross margins of an activity can be changed from its sample mean without affecting the sample variance.

[5] The total gross margin distribution of a farm plan will be approximately normal if the individual activity gross margin distributions are approximately normal. This is a demanding requirement and fortunately the Central Limit Theorem is applicable when sufficient numbers of activities enter farm plans and the activity gross margins are independent over time.

coefficients used can be regarded as nonstochastic or subjective parameters, then such probability statements are easily derived using tables for the normal deviate statistic [3, 12, 16]. Baumol [2] has used this approach to confine attention to those efficient E-V solutions for which an appropriate lower probability boundary is downward sloping for increases in E. Actually, the t distribution may be used to derive similar statements when only sample variance-covariance coefficients are available providing the forecasted gross margins are nonstochastic or subjective parameters.

(b) The variance V is totally specified by the variance-covariance coefficients; and when subjective values of these parameters are available, the variance is no longer estimated from the sample of observed gross margin outcomes. That is, equation (1) is applicable and need not have a direct relationship with equation (5) or (6).

(c) The criterion is consistent with the Separation Theorem and allows more general solution to the farm diversification problem given a riskless option [13].

Problems arise in applying the criterion, however, in that available quadratic programming computer codes with the necessary parametric option are of limited dimensions and uncertain performance.[6] The question arises whether alternative criteria might not be available which have most of the desired properties of the E-V criterion but which are easier to handle computationally. The expected income-mean absolute income deviation criterion is proposed to this end.

The Expected Income-Mean Absolute Income Deviation Criterion

Assuming the same sample data are available as for equation (6), the mean absolute income deviation (denoted by A) may be defined as follows.

$$(7) \qquad A = \frac{1}{s} \sum_{h=1}^{s} \left| \sum_{j=1}^{n} (c_{hj} - g_j) x_j \right|$$

A is an unbiased estimator of the population mean absolute income deviation [11].

Using A as a measure of uncertainty, it is reasonable to consider E and A as the crucial parameters in the selection of a farm plan and to define efficient E-A farm plans as those having minimum mean absolute income deviation for given expected income level E. As with the E-V criterion, such an E-A criterion is consistent with the Separation Theorem and with the derivation of probability statements with respect to the likelihood of occurrence of different income levels for a given farm plan. Assuming approximate normality and that the forecasted gross margins are nonstochastic or subjective parameters, the latter may be derived by use of tables for Herrey's H statistic [11]. They may also be derived using the variance of the farm plan calculated ex post using equation (6).

The mean absolute income deviation also considers interrelationships between activity gross margins by recognizing the mutually exclusive nature of the sample vectors of activity gross margin outcomes together with their associated relative frequencies; but unlike the variance, this requirement cannot be relaxed when subjective information is available. Subjective information can be incorporated only through judicious selection of important gross margin outcomes and assignment of associated probabilities. In this respect the criterion is more closely related to the parametric game models [7] where the possible sets of gross margins are called states of nature and can be carefully defined along the lines suggested by McInerney [17]. When using subjective data in this way it is necessary to regard the data as a population.

The E-A criterion has an important advantage over the E-V criterion in that it leads to a linear programming model in deriving efficient E-A farm plans. To see this, observe that in equation (7) $1/s$ is a constant and it is therefore sufficient to minimize sA subject to the constraints (2), (3), and (4). To convert sA to a legitimate linear programming objective function, a procedure similar to that used by Ashar and Wallace [1] may be used. Define new variables

$$y_h = \sum_{j=1}^{n} c_{hj} x_j - \sum_{j=1}^{n} g_j x_j \qquad (\text{for all } h,\ h = 1, \cdots, s),$$

such that

$$y_h = y_h^+ - y_h^-$$

and

[6] Available programs tend to suffer severely from computer rounding errors arising with the parametric subroutine, and problems can arise with multiple solutions when the variance-covariance matrix is only positive semidefinite rather than positive definite as required [13].

$$y_h^+, y_h^- \geq 0;$$

that is, such that y_h, $(h=1, \cdots, s)$, are unconstrained in sign. Then, if y_h^+ and y_h^- are selected in some minimal way so that one or the other is zero, $|y_h| = y_h^+ + y_h^-$, $(h=1, \cdots, s)$. But we can do this concurrently while seeking optimal x_j, $(j=1, \cdots, n)$, in the following linear programming model.

$$\text{(8)} \qquad \text{Minimize } sA = \sum_{h=1}^{s} (y_h^+ + y_h^-)$$

such that

$$\text{(9)} \qquad \sum_{j=1}^{n} (c_{hj} - g_j)x_j - y_h^+ + y_h^- = 0 \qquad \text{(for all } h, h = 1, \cdots, s)$$

and

$$\text{(10)} \qquad \sum_{j=1}^{n} f_j x_j = \lambda \qquad (\lambda = 0 \text{ to unbounded})$$

$$\text{(11)} \qquad \sum_{j=1}^{n} a_{ij} x_j \leq b_i \qquad (\text{for all } i, i = 1, \cdots, m)$$

$$\text{(12)} \qquad x_j, y_h^+, y_h^- \geq 0 \quad (\text{for all } h, j)$$

The model can be solved on conventional linear programming codes with the parametric option and provides a set of farm plans that are efficient for expected income and mean absolute income deviation. Since the model minimizes sA, it will be referred to hereafter as the Minimization of Total Absolute Deviations (MOTAD) model.

Now, for a given farm plan,

$$y_h^+ = \left| \sum_{j=1}^{n} (c_{hj} - g_j)x_j \right|$$

when $\sum_{j=1}^{n} (c_{hj}-g_j)x_j$ is positive and zero otherwise. Thus, $\sum_{h=1}^{s} y_h^+$ is the sum of the absolute values of the positive total gross margin deviations around the expected return based on sample mean gross margins. Similarly,

$$y_h^- = \left| \sum_{j=1}^{n} (c_{hj} - g_j)x_j \right|$$

when $\sum_{j=1}^{n} (c_{hj}-g_j)x_j$ is negative and zero otherwise, so that $\sum_{h=1}^{s} y_h^-$ is the sum of the absolute values of the negative total gross margin deviations around the expected return based on sample mean gross margins. It follows then that $\sum_{h=1}^{s} y_h^+$ must be exactly equal to $\sum_{h=1}^{s} y_h^-$ if g_j, $(j=1, \cdots, n)$, are sample mean gross margins. This suggests an alternative formulation for the MOTAD model based on minimizing only the sum of the absolute values of the negative total gross margin deviations $\sum_{h=1}^{s} y_h^-$. This is easily done in the following linear programming model.

$$\text{(13)} \qquad \text{Minimize } \sum_{h=1}^{s} y_h^-$$

such that

$$\text{(14)} \qquad \sum_{j=1}^{n} (c_{hj} - g_j)x_j + y_h^- \geq 0 \qquad (\text{for all } h, h = 1, \cdots, s)$$

and

$$\text{(15)} \qquad \sum_{j=1}^{n} f_j x_j = \lambda \qquad (\lambda = 0 \text{ to unbounded})$$

$$\text{(16)} \qquad \sum_{j=1}^{n} a_{ij} x_j \leq b_i \qquad (\text{for all } i, i = 1, \cdots, m)$$

$$\text{(17)} \qquad x_j, y_h^- \geq 0 \qquad (\text{for all } h, j)$$

This formulation can also be solved by conventional linear programming codes with the parametric option and leads to identical results as the model (8)–(12) except that the numeric value of the objective function is $\frac{1}{2}sA$ rather than sA. Note that while the MOTAD formulation (8)–(12) generally involves $n+2s$ real activities, the formulation (13)–(17) requires only $n+s$ real activities. Since both formulations have $m+s+1$ constraints if the nonnegativity requirements are ignored, the MOTAD formulation (13)–(17) is to be preferred in terms of computational efficiency in deriving efficient *E-A* farm plans.

In the absence of a measured *E-A* utility function, final selection of a farm plan from an efficient *E-A* set must be left to the individual farmer concerned. When results are presented in probabilistic terms a farmer is unlikely to have any greater difficulty in considering an efficient *E-A* set of farm plans than an efficient *E-V* set.

The MOTAD Model as a Substitute for Quadratic Programming

So far the *E-A* criterion has been proposed as an alternative to the *E-V* criterion in the sense that a farmer's preferences among alternative farm plans might be described by an *E-A* utility function. Under some conditions, however, choice between these criteria is less

important in defining a programming model since they may be expected to lead to similar or identical farm plans. More specifically, suppose (a) that the total income variances and mean absolute income deviations are estimated from sample data (though this may be corrected for any price and yield trends or cycles and for subjective expectations with respect to the means) and (b) that the populations of possible income outcomes for farm plans are normally distributed. Then, by considering the sampling distribution of estimated variance and mean absolute income deviation parameters, it is possible to examine the statistical properties of the mean absolute income deviation as a substitute for the variance in deriving efficient E-V farm plans.

It has long been established that when sampling from a normal distribution, the population standard deviation can be estimated with the statistic $d(\pi s/2(s-1))^{1/2}$ where s is the number of observations in the sample, $\pi=22/7$, and d is the estimated mean absolute deviation (m.a.d.) [11]. This statistic is also an estimate of the population standard deviation when the population is only approximately normally distributed [4]. Now since $(\pi s/2(s-1))^{1/2}$ is a constant, and we are considering A as a sample m.a.d., it is apparent that when the total gross margin distributions are approximately normal, the MOTAD model generates efficient farm plans for this estimate of the population income standard deviation (s.d.). Quadratic programming derives the efficient farm plans for the more usual sample standard deviation estimate of the population standard deviation; hence, any differences in the reliability of results from the two models for the same sample data will, given normality, depend upon differences in the properties of these estimators.

Both estimators are unbiased, provided that $s-1$ degrees of freedom are used in computing the sample variance-covariance coefficients and s degrees of freedom in computing A. Differences may arise however, in the relative efficiency of the two estimators.

Fisher [6] has shown that for large sample sizes the estimated mean absolute deviation is only 88 percent as efficient as the estimated standard deviation in estimating the population standard deviation. That is, the relative asymptotic efficiency of the sample mean absolute deviation is 88 percent.

Mathematical properties for small samples are less established, though these are the most interesting for farm planning when working with short-time series data. A classical manual simulation study was reported by Davies and Pearson [4] in 1934. Using approximately normally distributed data from a cement mortar composition study, they tabulated the following standard errors of estimates in population standard deviation units for single samples:

Estimate of population s.d. based on:	Sample size								
	2	3	4	5	6	10	15	20	50
Sample s.d.	.603	.463	.389	.341	.308	.232	.187	.161	.101
Sample m.a.d.	.756	.525	.430	.373	.334	.250	.201	.173	.108

The standard error of the sample mean absolute deviation was also found to tend to a value of 1.07 times the standard error of the sample standard deviation. The square of this ratio is approximately 1.14 which is consistent with Fisher's asymptotic efficiency value of 88 percent (that is, (100/1.14 percent)). Similar calculations for the above data give some indication of the relative efficiency of the sample mean absolute deviation for small samples:

	Sample size								
	2	3	4	5	6	10	15	20	50
Relative efficiency of sample m.a.d. (percent)	64	77	82	84	85	86	87	87	87

Since both estimators are unbiased and asymptotically normally distributed, these figures provide a rough but useful guide to the relative reliability of the two estimators [4]. The sample standard deviation always comes out best, being the minimum variance estimator, but its superiority is sufficiently marginal for sample sizes greater than 4 or 5 to justify consideration of the sample mean absolute deviation.

In the quadratic programming problem we seek to select a subset of farm plans from the set of all feasible plans having the property that, for given population E, the population variance (or equivalently, the population standard deviation) is minimum. In using sample data two sources of error may arise. We may select the wrong farm plans and/or we may incorrectly estimate the efficient E-V population function. Incorrect selection of the farm plans will in general imply incorrect estimation of the efficient E-V population function, but the reverse is not necessarily true. Errors in the selection of farm plans depend not only on the imputed variance for given E but also on the sensitivity of the "true" efficient farm

plans to changes in V for given E and on the rigidity of the farm constraints in forcing the farm plans. Either consideration could lead to the correct farm plans despite errors in the imputed variances, though the latter is more likely.

An inefficient estimator of V implies greater possible error in both sources. Quadratic programming utilizes the most efficient estimator of V, hence is subject to the least expected error. The MOTAD model on the other hand uses an estimator of V that at best may be only 88 percent as efficient, and in general the results cannot be expected to be as reliable. Note that both models use the same estimate of E; hence there can be no discrepancies in reliability on this ground. However, the possible rigidity of farm constraints in forcing farm plans may considerably enhance the reliability of the MOTAD model in selecting the correct farm plans. Further, since the variance of farm plans derived with the MOTAD model can be calculated ex post using equation (6), it is quite possible to generate almost identical farm plans and E-V efficiency functions for the same sample data with both techniques. This conclusion has been borne out by the author through actual application of both models to fresh market vegetable farms in New York and Florida operating under stringent market outlet constraints for individual crops. A less constrained and therefore more interesting example is presented at the end of this paper. Such results cannot be generalized, however; and in considering the MOTAD model as a substitute for quadratic programming in developing efficient E-V farm plans, it is well to be prepared for some loss in the reliability of the results.

It must be stressed that the above relationships hold only when the populations of possible income outcomes for farm plans are approximately normally distributed and when estimates of V and A are based solely on sample data. These requirements are not unreasonable in practice. Most farm situations that justify sophisticated programming techniques are likely to involve a sufficient number of activities so that approximate normality holds by the Central Limit Theorem. Further, subjective information can rarely be gleaned from farmers to supplement sample data on the dispersion and interrelationships of gross margin distributions. It seems reasonable to conclude that the MOTAD model may have considerable potential as an alternative computational procedure to quadratic programming in deriving efficient E-V farm plans, particularly when an adequate quadratic programming code is not available. The MOTAD model also has additional features that make it desirable as a substitute computational procedure, perhaps even when a quadratic programming code is available. First, it may lead to much smaller problems for complex farm organizations. The quadratic programming model generally invokes $m+n$ constraints and real activities, but the MOTAD model formulation (13)–(17) requires only $m+s+1$ constraints and $m+s$ real activities.[7] Second, while quadratic programming does provide dual information on the marginal values of constraints and activities, these values do not hold over any specified intervals [19]. The MOTAD model is therefore better adapted for post-optimality analysis.

When subjective information is available with respect to the dispersion and interrelationships of activity gross margins (a farmer may be willing to offer information about the probabilities of different gross margin outcomes, for example), it can be incorporated only at the expense of losing the sampling properties of input data, and the above relationships do not hold. While this does not preclude the possibility of getting similar results from the quadratic program and MOTAD models, the latter cannot be rigorously justified as a substitute to quadratic programming in deriving efficient E-V plans.

Semivariance Considerations

The variance as a measure of uncertainty weights total gross margin observations according to the square of their deviation from the mean. That is, E-V utility implies increasing marginal disutility the larger the total gross margin deviation from the mean. A direct consequence of this weighting procedure is that the contribution of negative total gross margin deviations to the variance need not be equal to the contribution of the positive total gross margin deviations. More specifically, assuming sample data, the negative semivariance

$$\frac{1}{s-1}\sum_{h=1}^{s}\left[\mathrm{Min}\left\{\sum_{j=1}^{n}(c_{hj}-g_j)x_j,\ 0\right\}\right]^2$$

need not be equal to the positive semivariance

$$\frac{1}{s-1}\sum_{h=1}^{s}\left[\mathrm{Max}\left\{\sum_{j=1}^{n}(c_{hj}-g_j)x_j,\ 0\right\}\right]^2.$$

[7] The author is indebted to Wilfred Candler for this suggestion.

In fact, an inequality will generally hold unless the population total gross margin distributions are symmetric.

This is important because even when an individual does weight income deviations on a quadratic basis there may be no a priori reason to assume that he attaches any disutility to positive income deviations, so that using an E-V criterion may lead to unnecessarily conservative farm plans. Markowitz [15] suggested that when total gross margins cannot be expected to be symmetrically distributed, an expected return-negative semivariance criterion might provide a better approximation of an individual's utility function. In effect, Markowitz suggested minimizing the negative semivariance subject to the constraints (2), (3), and (4) to generate a set of efficient E-negative semivariance farm plans. However, such a model can be solved only through Monte Carlo simulation techniques which are unlikely to be a practical procedure for most farm planners.

These problems do not arise if an individual weights income deviations on a linear basis, as presumed in the E-A criterion, because the negative income deviations always make an equal contribution to the positive income deviations in the mean absolute deviation measure of uncertainty. That is,

$$\frac{1}{s}\sum_{k=1}^{s} y_k^- = \frac{1}{s}\sum_{k=1}^{s} y_k^+$$

regardless of the shape of the total gross margin distributions. Thus, even if a farmer does not attach any disutility to positive total gross margin deviations, the E-A criterion is still appropriate in defining a programming model since it leads to the same efficient set of farm plans as a model based on an expected return-mean absolute negative deviation criterion. This fact was used in constructing the MOTAD formulation (13)–(17). It follows that if the E-A criterion is an acceptable approximation to a farmer's utility function, the MOTAD model provides a single alternative to both the quadratic and semivariance models for all types of total gross margin distributions.

While the E-A criterion avoids semivariance type problems, it does mean that a linear substitute to the semivariance model cannot be based on absolute deviations for generating efficient E-negative semivariance farm plans when a quadratic utility weighting procedure is appropriate. In this case the only linear alternatives appear to be the parametric game models [7], but their statistical properties as possible computational substitutes to the semivariance model are not known.

A Numeric Illustration

To illustrate some of the concepts discussed, the quadratic programing and MOTAD models are applied to a small numeric example.

The example comprises four vegetable activities: carrots (x_1), celery (x_2), cucumbers (x_3), and peppers (x_4); and three less-than or equal-to constraints on the available acreage of land (b_1), hours of labor (b_2), and a rotational and market outlet constraint (b_3). The technical requirements coefficient matrix A and constraint vector b are

$$A = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 25 & 36 & 27 & 87 \\ -1 & 1 & -1 & 1 \end{bmatrix}, \qquad b = \begin{bmatrix} 200 \\ 10{,}000 \\ 0 \end{bmatrix}$$

The constraint b_3 requires that the total acreage of celery and peppers be less than or equal to the total acreage of carrots and cucumbers.

A time series of gross margins was obtained from an actual fresh market vegetable farm in Florida (Table 1). The estimated covariance matrix is

$$\begin{bmatrix} 11{,}264 & -20{,}548 & 1{,}424 & -15{,}627 \\ -20{,}548 & 125{,}145 & -27{,}305 & 29{,}297 \\ 1{,}424 & -27{,}305 & 10{,}585 & -10{,}984 \\ -15{,}627 & 29{,}297 & -10{,}984 & 93{,}652 \end{bmatrix}$$

which explicitly expresses the interrelationships captured between the six row vectors of Table 1. Sample mean gross margins are used as forecast values.

A tableau of constraints and real activities for the MOTAD model formulation (13)–(17) is presented in Table 2. Note that the activity

entries for the rows t_h, $(h=1, \cdots, 6)$, are the activity gross margin deviations from their sample means in the hth year. The set of efficient E-A solutions occurring at change in basis for this model was obtained (Table 3), as were the quadratic program solutions (Table 4). In both cases the last solution is identical with a conventional linear programming solution obtained for the average gross margins.

The example chosen permits considerable flexibility in the cropping plans while retaining feasibility to the farm constraints. Further, there are insufficient activities to expect total gross margins to be approximately normally distributed by the Central Limit Theorem. These considerations suggest that the MOTAD model need not be a good substitute for the quadratic programming model in generating the set of efficient E-V farm plans for this problem. However, a comparison of quadratic programmed and MOTAD model solutions (Table 4) indicates a surprising similarity of results. In particular, although some discrepancies in crop acreage occur, these are not sufficient to have any marked effect on the corresponding standard deviations. In fact, the E-V pairs are almost identical for the two models.

Conclusions

A linear decision criterion using the expected return and the mean absolute income deviation has been proposed as an alternative to the E-V and E-semivariance criteria for farm planning under gross margin uncertainty. The suggested criterion utilizes similar data on possible activity gross margin outcomes and has desirable properties as a decision criterion for farm management research and extension purposes. In addition, it leads to farm planning models that can be solved on conventional linear programming codes with the parametric option. This enables easier and less expensive solution of large-dimensioned problems and permits better post-optimality analysis. Under quite common empirical conditions, the proposed MOTAD model for the E-mean absolute income deviation criterion has been justified as an approximate computational procedure for deriving efficient E-V farm plans when a good quadratic program is not available.

A Simultaneous-Equation Model of Spatial Equilibrium and Its Application to the Broiler Markets*

Tsoung-Chao Lee and Stanley K. Seaver

The simultaneous-equation approach is used to formulate a positive spatial equilibrium model consisting of linear behavioral and definitional equations and bilinear equilibrium conditions. In contrast to the normative Takayama-Judge quadratic spatial equilibrium model, the positive model leads to a smaller simplex tableau and permits evaluation of the effect of predetermined variables on spatial equilibrium. The model is applied to structural changes of broiler markets. Spatial equilibrium multipliers are presented to show the interregional competition of the existing broiler markets.

In recent years spatial equilibrium analysis has been formulated as a quadratic programming problem. Takayama and Judge [12] derived the model by maximizing the so-called "net social payoff" subject to the linear demand and supply functions. Their study is largely conceptual in the sense of assuming that linear demand and supply functions are known or given. Many researchers [7, 8, 14], when applying this model, have estimated demand and supply functions based on methods that are exogenous to the structure of spatial equilibrium. The supply function of each market may be estimated as a single regression equation independent of the supply functions in other markets and of the demand function in the same market [14]. Or market supply functions may be estimated by the micro-to-macro buildup approach from the linear programming step supply functions [8]. The demand functions are usually derived [7, 8] from Brandow's demand elasticities or slopes that were estimated in 1961 [2].

In view of previous work, spatial equilibrium models are often used normatively to show how the output at many locations "should" flow to many consuming areas if competitive conditions are to be attained and costs minimized. However, no positive analysis of spatial equilibrium has been reported in the Journal. It should be emphasized that a positive analysis of spatial equilibrium should estimate the demand and supply functions simultaneously within the model in order to produce quantitative statements "describing" the existing competitive markets and to predict the future course of economic variables. Thus, one of the hypotheses in positive analysis is that the markets are spatially competitive, which of course is subject to statistical test.

Within the context of positive economics, equilibrium conditions and definitional equations place a restriction on the parameters that are being estimated. To deal with economic variables generated by a spatially competitive system that is dynamic, stochastic, and simultaneous, a simultaneous-equation technique is required. It should be noted that if a simultaneous solution of exogenously estimated structural equations were intended as a positive analysis, it would be subject to Haavelmo's criticism.[1]

Broiler markets, in our analysis, are considered spatially competitive. Broiler production in the southern states has been increasing tremendously since 1957, while the northeast region has changed from a surplus to a deficit area. It is believed that the change is associated with decreasing farm price of broilers and increasing feed price in the northeastern states relative to that of the southern states. In view of these changes we are interested in studying structural changes of the broiler economy. Specifically, the objective is to analyze the effect of a change in feed price in each region on (1) broiler production, (2) price of broilers, (3) shipment of broilers among regions, and (4) derived demand for feed.

In this paper (1) a general simultaneous-equation model of spatial equilibrium is presented and discussed, and (2) a specific model of spatial equilibrium is proposed to study the

[1] "A most dangerous procedure in estimating parameters in systems of stochastic equations is to fit each equation separately without regard to the fact that the variables involved are, usually, assumed to satisfy, simultaneously, a number of other stochastic relations" [6].

structural change of broiler markets in the aggregate with emphasis on regional interelationship. There is no intention of studying the broiler industry at the producing or retail firm level.

Methodology

The simultaneous-equation model

Assuming n spatially separated markets or regions, we hypothesize the linear demand and supply functions for a single commodity in the ith region as

$$(1) \quad D_i = \alpha_i p_i + a_{i0}z_0 + a_{i1}z_1 + \cdots + a_{ik}z_k + u_i$$

and

$$(2) \quad S_i = \beta_i p_i + b_{i0}z_0 + b_{i1}z_1 + \cdots + b_{ik}z_k + v_i$$

where p_i is the price and the z's are predetermined variables such as income, factor input price, etc., and u_i and v_i are stochastic variables which may be assumed to have zero means, constant variances over time, and zero autocorrelations, but may not be independent of price. The parameters are α, β, a's and b's. There are n such supply and n such demand equations.

Since spatial equilibrium models consider the interregional flow of commodities, demand and supply may be decomposed into shipments:

$$(3) \quad D_j = \sum_i x_{ij} \qquad j = 1, 2, \cdots, n$$

and

$$(4) \quad S_i = \sum_j x_{ij} \qquad i = 1, 2, \cdots, n$$

where x_{ij} denotes quantity shipped from ith region to the jth region. There are n equations for each type of (3) and (4). Before reaching equilibrium, commodity flow is considered possible whenever the price differential in any pair of regions exceeds the transportation costs t_{ij}. Thus, whether the product in the ith region should be sold in the jth region depends on the following per unit loss (or per unit gain):

$$(5) \quad r_{ij} = t_{ij} - (p_j - p_i) \qquad \text{all } i, j$$

There are n^2 such definitional equations. Since in the same region the transportation cost is zero, only $n(n-1)$ equations are required to determine $n(n-1)$ interregional flows of commodities.

For a competitive equilibrium to hold, there must be no profit ($r_{ij}=0$) or there must be no flow of commodities ($x_{ij}=0$).[2] There are $n(n-1)$ equilibrium conditions:[3]

$$(6) \quad r_{ij}x_{ij} = 0 \qquad \text{for } i \neq j$$

In total there are $2n+2n^2$ equations with the same number of jointly dependent variables, which specifies a complete system of equations.[4]

The model as specified is for a single product case, but it may be generalized into multiproduct general equilibrium. Supply and demand functions may be formulated as functions of many commodity prices and some predetermined variables.

In summary, the spatial equilibrium model involves equations for demand and supply (1) and (2), commodity distributions (3) and (4), and equilibrium conditions (6), in which the loss variable (or profit margin) is defined in (5).

Identification and estimation

The demand and supply functions of the model are identifiable as long as transportation costs t_{ij}'s do not appear in the demand and supply functions. To obtain the consistent estimates of the parameters of demand and supply that are identifiable in a system of equations, the simultaneous estimation approach should

[2] These two assertions are equivalent to the Kuhn-Tucker conditions of the quadratic programming formulation of spatial equilibrium. See [12].

[3] In practice, because of the error in measurement and imperfect competition, the sample data do not necessarily fulfill this condition, especially in the supply-demand adjustment over space for short periods of time. If we adopt this assumption, we may redefine the per unit loss function as

$$(5a) \quad r_{ij}^* = (t_{ij} + c_{ij}) - (p_j - p_i) + d_{ij}$$

where c_{ij} denotes opportunity cost defined as the possible profit that the producers would earn if they engaged in other economic activities with the same effort as shipping one unit of the commodity from i to j, and d_{ij} is the possible error in measuring prices. Thus, c_{ij} is due to imperfect competition and d_{ij} to errors of observation which may have zero expectation. The equilibrium condition is then

$$(6a) \quad r_{ij}^* x_{ij} = 0.$$

[4] In augmented model there may be n^2 equations for each set of (5) and (6) including r_{ii}'s, and the demand price p_i may be different from supply price (say p^i); thus there will be $4n+2n^2$ equations and $4n+2n^2$ variables, and the system is still complete. An abbreviated model may be obtained if equations (3) and (4) are substituted into equations (1) and (2). In this case, there will be only $2n^2$ equations and $2n^2$ variables, and the model is still complete. See Table 1.

be used. If the system of equations is large, with many markets or products involved, and if time series data available are rather short, principal components of predetermined variables may be used as instrumental variables [9].

Spatial equilibrium and static analysis

In the model specified above, there are $2n+2n^2$ equations in which $n(n-1)$ equations are bilinear (equation (6)). There will be $2^{n(n-1)}$ solutions satisfying equations (1) through (6) including any possible real and complex number solutions. The complex number solution is not possible because the bilinear equations are homogeneous and may be factorized into two linear equations. However, among $2^{n(n-1)}$ real solutions, most of the basic solutions in which some variable or variables may take negative values are not economically feasible solutions. Thus, to obtain an economically meaningful equilibrium solution, nonnegativity restrictions must be imposed on all jointly dependent variables. As a consequence, questions about existence and uniqueness of spatial equilibrium arise. However in the light of theorems of Arrow and Debreu [1], Debreu [3], and McKenzie [10], we may tentatively conclude that if the economy has only one equilibrium, the system of equations specified above for that economy will have a unique nonnegative solution.

To solve for the jointly determined variables, we may simplify the model by equating equations (1) and (3), and (2) and (4) to reduce the number of variables and equations to obtain

$$(7) \quad \sum_{i=1}^{n} x_{ij} - \alpha_j p_j = \sum_{m=0}^{k} a_{jm} z_m + u_j \qquad \text{all } j$$

$$(8) \quad \sum_{j=1}^{n} x_{ij} - \beta_i p_i = \sum_{m=0}^{k} b_{im} z_m + v_i \qquad \text{all } i$$

Now only equations (7) and (8) together with equations (5) and (6) must be solved for nonnegative shipments x_{ij}, prices p_i and "profit margins" r_{ij}. An example of a system of equations is given in Table 1, in which $D_i(z)$ and $S_i(z)$ represent functions of predetermined variables or, respectively, the right hand side of (7) and (8) except disturbances. The procedure for obtaining a solution is equivalent to Wolfe's quadratic programming algorithm [15], which was also adopted by Takayama and Judge [12]. Thus, solving the 2nd order simultaneous equations (1) through (6) is equivalent to solving the Takayama-Judge quadratic programming problem,[5] and the existence and uniqueness of a spatial equilibrium are further confirmed.

When the equilibrium solution is obtained, those variables taking on a zero value in (6) may be deleted and the set of reduced form equations obtained. It is important to know that the reduced form equations are known only when direction of commodity flows are known; that is, those x_{ij}'s which are zero are known and may be deleted. However, we do not necessarily know the precise quantity of flow. Direction of flow is primarily determined by the magnitude of exogenous variables, t_{ij}'s and z_i's. Within a certain range of exogenous variables, although the quantity of shipment may be different, direction of shipment may remain unchanged. Therefore, coefficients of reduced form equations are rather stable in the neighborhood of equilibrium.[6] It is reasonable to study the

[5] The exactly identical simplex tableau as Takayama-Judge's may be obtained if demand and supply prices are independently defined. In this paper we prefer to have the simplex tableau written in the most compact form, yet containing the necessary information.

[6] Reduced form coefficients are "locally stable" with respect to an infinitesimal change of an exogenous variable

effect of infinitesimally small changes in t_{ij} or z_i on x_{ij}, r_{ij}, and p_i by taking the partial derivative of say p_i with respect to z_j from reduced form equations.

Empirical Analysis for Broilers

A model for broilers

Alternative relationships among variables were formulated to estimate supply functions of broilers in the Northeast, the South, and the rest of the United States.[7] In most cases, estimated price coefficients are negative and not statistically significant from zero. At the national level, it has been shown that change of broiler supply from the preceding year is positively related to lagged profitability [13, p. 10]. Thus, current supply of broilers is related to the preceding year's supply and profitability. If spatial flow of broilers is also considered, lagged supply in other regions may also affect current regional supply. In the final analysis, therefore, regional supply is hypothesized as a function of lagged national supply Q_{t-1} and lagged regional profitability R_{it-1}:

$$(9) \quad S_{it} = b_{i0} + b_{i1}Q_{t-1} + b_{i2}R_{i\ t-1} + v_{it}$$

where v_{it} is the disturbance term. Lagged regional profitability in this study is defined as the lagged broiler price (p_{it-1}) minus the major cost of production. The major cost is calculated as regional lagged feed price (p_{fit-1}) multiplied by lagged feed per pound of broilers (F_{it-1}).[8] In equation form, the profitability relation is

$$(10) \qquad R_{i\ t-1} = p_{i\ t-1} - F_{i\ t-1}\ p_{fi\ t-1}$$

It implies that producers will respond to profitability but are indifferent as to whether the increase in profitability is due to an increase in broiler price or decrease in feed price, or improvement in technology.

On the demand side, aggregate quantity demanded in each region is postulated as a linear function of current broiler price p_{it} and current total national disposable income y_t:

$$(11) \qquad D_{it} = a_{i0} + \alpha_i p_{it} + a_{i1}y_t + u_{it}$$

where u_{it} is the disturbance term.[9]

The definitional equations include six equations of the distribution activities (3) and (4), and six equations of the per unit loss (5). The six equilibrium conditions are defined by equation (6). Thus there are in total 18 equations, in which 12 equations are linear and six equations are bilinear.

The estimated structural equations and spatial equilibrium

The two-stage least squares method is used in estimating the parameters. The results, given in Table 2, show that the lagged quantity is a significant variable in explaining current supply at the 1 percent significance level. Profitability is significant only in the South at the 1 percent significance level. All the F-tests show significant association between regressand and regressors[10] at the 1 percent significance level. In the demand equations variables are highly associated, coefficients are significant, and signs are compatible with theory.

The equilibrium solution[11] for each year is solved when all predetermined variables are given by numerical values. The solutions are consistent with the fact that in 1956 the northeast region was self-sufficient with essentially

but this does not imply being "globally stable." If the change in z_i or t_{ij} is not infinitesimally small, it is quite possible that the direction of commodity flow may change; and a new equilibrium must be relocated to determine the flow pattern and the new set of reduced form equations associated with it.

[7] The northeast region consists of New England, Mid-Atlantic, and Virginia. The southern region includes North Carolina, South Carolina, Georgia, Florida, Alabama, Mississippi, Louisiana, and Arkansas. Hereafter, the North will be region one; the South, two; and the rest of the United States, three.

[8] The cost analysis would be in detail if other costs, such as chick costs, medication and grower payments, etc., are included. However, from the regional cost advantage point of view, only relative profitability between regions is necessary. Hence, only feed costs are included in the regional profitability function. Other components of total costs vary between regions in almost the same manner as do feed costs. Feed costs represent over 60 percent of the total cost of a finished bird and are approximately 60 percent of total costs even after adjusting feed prices for integrated operations.

[9] Regional disposable income was used in the initial analysis and then deleted in the final analysis because (1) regional disposable income is highly correlated with national disposable income, and alternative results are very close; and (2) if the regional disposable income is used, the reduced form equations suffer from multicollinearity and are very expensive in terms of degrees of freedom.

[10] The terms regressand and regressors are used instead of conventional dependent and independent or explanatory variables because (1) our regressors are not necessarily independent but are jointly dependent, and (2) some of the regressors in the second stage estimation are the "calculated" value of jointly dependent variables. For the distinctions among terms, see Goldberger [5, pp. 213–215].

[11] Equilibrium solutions are computed merely for the purpose of forecasting, and no normative connotation is attached [11, p. 8]. Deviations of the data from equilibrium solutions are only an indication of the goodness-of-fit and not a normative critique of the competitive markets.

Table 2. Estimated regional supply and demand relations for broilers (1956-1967) by two-stage least squares

Region	Supply or demand	Constant term	National disposable income	Lagged national supply	Regional farm price	Lagged regional profit-ability	R^2	Computed F statistic[a]
		millions of pounds	*billions of dollars*	*millions of pounds*	*cents per pound*

[a] The value in the F-table for degrees of freedom (2,9) at the 1 percent significance level is 8.02.
[b] Figures in parentheses are standard errors.

no receipts of broilers from the southern states. In 1957 the northeast region became a deficit area and in 1967 approximately 30 percent of the broilers consumed came from the southern states. Comparing the predicted equilibrium and actually measured prices, we find that differences are in general small. The equilibrium solution for 1967 is forecast and given in Table 3.

Table 3. The equilibrium solutions for broiler markets in 1967[a]

Predetermined variables	Jointly determined variables
$Q_{t-1}=6191$ million lbs.	$p_1=20.61$¢ per lb.
$y_t=536.815$ billion dollars	$p_2=18.96$¢ per lb.

	$r_{13}=1.86$¢ per lb.
	$r_{31}=1.16$¢ per lb.
	$r_{32}=2.60$¢ per lb.
	$r_{21}=0$ per lb.
	$r_{23}=0$ per lb.

[a] The representative points for three regions are New York City; Gainesville, Georgia; and Chicago.

The direct effect and the spatial equilibrium multipliers

The conventional way to study consumers' behavior is to determine price and income elasticities from demand equations. The slope of the demand equation indicates only a direct effect within a single sector of the economy, especially when price or quantity is simultaneously determined with other sectors. Thus, elasticities computed from a single structural equation may be considered as "partial" elasticities.

Ceteris paribus, partial price and income elasticities are evaluated at equilibrium prices and quantities.[12] The results, given in Table 4, indicate that elasticities are changing from time to time because of simultaneous shifting of demand and supply.[13]

Coefficients of the linear reduced form equa-

[12] In most of the empirical studies the elasticities are evaluated at the average price. Since the demand and supply are shifting over time, it is more appropriate to evaluate them at equilibrium prices and quantities.

[13] The elasticities in 1956 may be compared with the average monthly elasticities of the period 1953–1963 given by Farris and Darley [4]. In making comparison, however, one should bear in mind that their elasticities were converted from flexibilities computed at mean prices and quantities for 1953–1963. In addition, all data were on a per capita basis, and estimates were obtained by single equation ordinary least squares.

Table 4. Estimated "partial" price and income elasticities for broilers at farm level, by regions, 1956-1967

Year	Price elasticities			Income elasticities		
	North	South	Rest of the United States	North	South	Rest of the United States
1956	−1.03	−0.94	−0.81	1.02	1.24	1.09
1957	−0.98	−0.82	−0.71	1.02	1.18	1.05
1958	−0.74	−0.62	−0.56	0.91	1.06	0.97
1959	−0.60	−0.49	−0.45	0.86	1.00	0.92
1960	−0.53	−0.43	−0.40	0.83	0.97	0.90
1961	−0.48	−0.39	−0.36	0.82	0.95	0.89
1962	−0.44	−0.35	−0.33	0.82	0.94	0.88
1963	−0.47	−0.38	−0.35	0.85	0.97	0.91
1964	−0.44	−0.36	−0.33	0.86	0.98	0.92
1965	−0.49	−0.39	−0.36	0.92	1.02	0.96
1966	−0.39	−0.31	−0.29	0.89	0.98	0.93
1967	−0.34	−0.27	−0.25	0.87	0.97	0.92

tions, which indicate the "total" effect of a change in predetermined variables on current endogenous variables after taking account of interdependencies among current endogenous variables, may be called "multipliers." Since the equilibrium solution pattern of 1956 is different from the other years in the series, the impact multipliers [5, pp. 374–375] are computed for the shipping pattern of the period 1957 through 1967 and are given in Table 5.

Since supply equations do not depend on current prices, the model may be considered a recursive system. For example, the data in Table 5 indicate that if profitability in the northeast region is increased by one cent with other predetermined variables being constant, supply in the northeast region will increase by 7.11 million pounds. However, this increase in supply in the Northeast will cause a decrease in supply price of 0.08 cents per pound. The flow of commodities will result in a decreased shipment of broilers from the South to the North by 4.61 million pounds. The South will increase shipments to the rest of the nation by 3.54 million pounds and increase by 1.07 million pounds the quantity of broilers sold in the South. As a result, the South and the rest of the nation will decrease the price by 0.08 cents to stimulate more consumption. The consumption in each region will increase by 2.50, 1.07, and 3.54 million pounds for the North, the South, and the rest of the United States, respectively.

"Total" elasticities, which take into account the interdependence of current endogenous variables, are evaluated at equilibrium in 1967 (Table 6). The results indicate that elasticities are small.

The effect of change in feed price on broiler production and derived demand of feed

The effect of change in feed price on broiler production may be evaluated by

$$\frac{\partial S_{it}}{\partial p_{fi\,t-1}} = \frac{\partial S_{it}}{\partial R_{i\,t-1}} \cdot \frac{\partial R_{i\,t-1}}{\partial p_{fi\,t-1}} = -\frac{\partial S_{it}}{\partial R_{i\,t-1}} \cdot F_{i\,t-1} \tag{12}$$

With 1967 technology, if feed price decreases by 1 cent per pound, production in the North will increase 24.82 million pounds; production in the South will increase 117.75 million pounds; in the rest of the nation, by 21.35 million pounds. The increase in feed demanded would be 86.62, 620.33, and 74.52 million pounds for the North, the South, and the rest of the United States, respectively. The elasticities of supply of broilers and derived demand of feed with respect to feed price are identical: −.10, −.21, and −.09 for the North, the South, and the rest of the United States, respectively.

Conclusions

Spatially competitive markets may be positively analyzed. With a certain level of statistical significance, the simultaneously estimated demandand supply functions along with equilibrium conditions describe how interregional competition has developed and therefore provides a basis for forecasting, if past structure prevails in the future. In addition the model provides equilibrium multipliers which answer questions arising from comparative static analysis.

The estimated demand functions for broiler markets are compatible with consumer behavior. Income slowly stimulates broiler consumption in each region. Supply is largely predetermined by the previous year's production with an insignificant amount of adjustment to the previous year's profitability.

The simultaneous shifting of demand and supply has a tendency to decrease equilibrium prices and increase broiler production. In 1967 interregional shipment of broilers equalized farm prices at approximately 19 cents per pound of ready-to-cook broilers in the South, with prices in other regions higher by transportation costs.

Spatial equilibrium multipliers indicate that insignificant increases in broiler prices result from increasing consumer income. As lagged profitability increases, broiler prices will decrease. The negative effects of lagged national supply on prices has important implications for broiler supply control.

The forecasted equilibrium solutions are quite close to the observed values despite the fact that the study is highly aggregated over time and space and does not take into account seasonality and normative aspects of the production process. However, it does give a positive picture of the existing and changing structure of interregional competition for broilers.

From Hedging to Pure Speculation: A Micro Model of Optimal Futures and Cash Market Positions*

RONALD W. WARD AND LEHMAN B. FLETCHER

A theoretical model of optimal firm decisions in cash and futures markets that includes both primary product producers and marketing firms is presented. The generalized model of production and marketing decisions under risk is applied to both short and long hedging and speculation. Hedging and speculation are given precise definitions. Speculation exists when a firm's futures position exceeds the 100 percent hedging level or when it does not provide hedging possibilities in conjunction with the cash market position. Comparisons between hedging on futures markets and forward contracting are made. Live beef futures are used to show how transformation costs for nonstorable commodities should be treated in the same manner as storage costs for storable commodities.

THE DIFFERENCE between the current cash price for grain and the price for delivery at some future date is interpreted as the market price of storage. When processing is involved, as for soybeans, the spread between spot soybeans and forward soybean products is seen as the market price for the required storage and processing services [6]. For cattle the spread between cash prices for feeders and feed and future prices for fed cattle represents the market price for feedlot services [5]. In each instance, a product transformation (i.e., storage and/or processing services) is involved, and the price of these transformation services is the linkage leading to the simultaneous determination of cash and futures prices. Existing theories of futures trading in relationship to cash markets have been incomplete when applied to the individual decision maker, however. In this paper we try to clarify the role of futures markets in production and marketing decisions under risk. We also attempt to provide a more general theoretical model than is now available for optimal firm decisions in cash and futures markets by considering both primary product producers and marketing agencies.

McKinnon [4] has developed a theory of futures utilization by primary producers as a hedge against *production* and *cash price risks*. His derivation of optimal hedges follow from the assumption that producers wish to minimize the variance of income. He answers the following question: Given a specified level of input X, what is the optimal hedge? Stein [8] outlined a theory explaining the allocation between hedged and unhedged holding of stocks. Given a utility map relating expected returns and risk, the optimal combination of hedged to unhedged stocks can be found. The optimal hedging proportion provides the maximum attainable level of utility for the inventory holder.

Johnson's reformulation of the theory of hedging [3] suggested that hedging and speculative activities are often combined in the actions of a decision maker.

In none of these articles, however, have the arguments exhausted all of the market alternatives; i.e., a more generalized theory applicable to both short and long hedging and speculation by producers and marketing firms is needed. We have incorporated much of the existing theory in this attempt to develop a more general micro model of optimal behavior in cash and future markets.[1]

We have made use of live beef futures for expository purposes [1, 2, 7]. The role of storage is less meaningful to beef futures trading than product transformation. Corn can be stored from one period to another, but feeder cattle are fattened and then slaughtered with only very limited storage possibilities. In both instances, however, a service has been performed that yields a final output different from the initial input. Transformation cost, therefore,

[1] This article could be expressed in a framework of portfolio theory, where portfolio analysis is generally viewed as a decision mechanism for selecting assets with uncertain yields. Define a vector $z=(x, x_f)$, where x and x_f are coordinates of possible cash and futures markets and p_z is a vector of market returns that are unknown at the time of portfolio selection. Portfolio theory then establishes that a demand for z appears as $z_D=z(p_z, \mu_z, \sigma_z, \kappa)$, where the vectors μ_z = mean, σ_z = var-cov matrix and κ is some constant. We have limited our selection theory to one cash and one futures market, yet this restriction will enable us to show precisely the optimal market positions that would not be immediately evident under the general portfolio approach.

should be treated in the same manner as storage cost; that is, both are service costs incurred between time periods t and $t+k$ [5].

Our model of individual decision making will show explicitly: (1) the alternative futures and cash market positions that can be established by producers and marketing firms; (2) the role of income, cost, risk, and expectations in the decision process; (3) optimal positions in the futures and cash markets; and (4) hedging and speculative positions in futures and cash markets. Part I presents the necessary assumptions, conditions, and theoretical framework; part II, the determination of optimal levels of the choice variables. A final section contains the conclusions and implications of the model, together, with some comparisons between hedging on futures markets and forward contracting for the individual decision maker.

I

Decision-making framework

Assume a finite number of decision makers operating in a purely competitive environment. Each market participant has a given occupation and has made the necessary capital investment for functioning in the cash market. The decision maker may be a feedlot operator who has previously made all necessary capital investments in feedlot facilities. His decision process then consists of making the appropriate decisions in period t for the optimal number of feeder cattle to purchase and the optimal futures position. This position in futures would be expected to be terminated k periods from t, where k is the time required for transformation of feeders into slaughter animals. In essence, the present decision theory will encompass only the short run, since the transformation (feedlot) capacity is taken as fixed.

Income and cost considerations

Each market participant can establish one or any combination of market positions in period t where X and X_f are the two choice variables representing *quantities* in the cash and futures markets. X is measured in *live animal units* of given *weight* and *quality*, and X_f is expressed in equivalent live animal units. Thus, the market positions can be summarized:

$X_f>0$ — a short position in futures contracts from period t to $t+k$ for contracts maturing in period $t+n$, $k\leq n$ (the decision maker sells beef futures during period t);

$X_f<0$ — a long position in futures contracts from period t to $t+k$ for contracts maturing in period $t+n$, $k\leq n$ (the decision maker buys beef futures during period t);

$X>0$ — cash market purchases in period t for commodity requiring k periods for product transformation (the number of feeder cattle purchased and placed in feedlot in period t);

$X<0$ — cash market quantities contracted in period t for delivery in period $t+k$, or cash market purchases *planned* in period t for period $t+k$ (the number of slaughter steers sold for deferred delivery or anticipated purchases of slaughter steers at $t+k$).

Market prices are expressed as:

P_t = cash price per unit of X (where $X\geq 0$) in period t (price of feeder cattle per animal in period t);

P_{t+k} = cash price per unit of *transformed* X in period $t+k$ (price of slaughter steers per animal in period $t+k$);

P_t' = cash market contracting price per unit of X (where $X<0$) in period t for delivery in period $t+k$;

F_t = futures price per unit of X_f in period t for contract maturing in period $t+n$;

F_{t+k} = futures price per unit of X_f in period $t+k$ for contract maturing in period $t+n$, $k\leq n$.

Each decision maker also incurs costs from his participation in the cash and futures markets. Define:

C = average cost of transformation and marketing of X;

C_f = average cost of futures position in X_f.

Prices P_{t+k} and F_{t+k} are unknown at period t; hence, they are assumed to be random variables where the mean and variance is known. The cash position may be either $X\geq 0$ or $X<0$; similarly, the futures position is either $X_f\geq 0$ or $X_f<0$. The absolute values of X and X_f indicate the magnitude of a market position while the signs of X and X_f identify the type of position.

Expected net income equations can now be defined:

$$E\pi(X\geq 0,\ X_f \gtrless 0)$$

$$= XE[P_{t+k}-P_t]-X_fE[F_{t+k}-F_t] - |X|C - |X_f|C_f \tag{1}$$

$$E\pi'(X < 0, X_f \gtreqless 0)$$
$$(2) \quad = XE[P_{t+k} - P_t'] - X_f E[F_{t+k} - F_t] - |X| C - |X_f| C_f$$

Equation (1) represents a decision maker's expected net income with both cash ($X \geq 0$) and futures ($X_f \gtreqless 0$) market positions. Equation (2) applies when forward contracting and anticipated purchases in the cash market ($X<0$) exist in conjunction with a futures position ($X_f \gtreqless 0$).[2] In either equation the decision maker cannot be both short ($X_f \geq 0$) and long ($X_f<0$) at the same time.

Decision-making risk

In this article, risk to the decision maker results from variations in realized net income when price expectations do not materialize. Each individual is assumed to be a risk averter in the sense that he will choose those market positions that minimize his risk for a given expected net income. Risk is then defined as the variance of net income. Given the combinations of expected net income and risk and the shape of the decision maker's preference function relating risk to expected net income, the format for determination of optimal market positions is set.[3]

II

Optimal market position for the short hedger

We assume that a market participant chooses his positions in the cash and futures markets at period t based on his price expectations. The goal of the decision maker is to maximize expected net income; however, since expected prices may not materialize, risk prevails and must be considered when establishing cash and futures positions. Thus, we use a trade-off approach between expected net income and risk as elements in the decision maker's utility function leading to the simultaneous determination of optimal positions in the cash and futures markets.

If the variance of net income is taken as a measure of risk, a theoretical risk function for net income (equation (1)) can be written:

$$(3) \quad \mathrm{Var}\,(\pi) = X^2\sigma_p^2 + X_f^2\sigma_f^2 - 2XX_f\rho\sigma_p\sigma_f$$

where

$$\sigma_p^2 = \mathrm{Var}\,(P_{t+k} - P_t) = \mathrm{Var}\,(P_{t+k} \mid P_t)$$
$$\sigma_f^2 = \mathrm{Var}\,(F_{t+k} - F_t) = \mathrm{Var}\,(F_{t+k} \mid F_t)$$
$$\rho = \sigma_{pf}/\sigma_p\sigma_f$$
$$= \text{correlation between } (P_{t+k} - P_t) \text{ and } (F_{t+k} - F_t).$$

This function assumes that σ_p^2, σ_f^2, and ρ are known and constant for the given decision maker. The greater (smaller) the positive correlation between cash and futures prices, the smaller (larger) risk will be. Risk also decreases as the variance of cash and futures prices decrease.[4]

This equation holds for any decision maker who establishes a futures position against a current position in the cash market ($X>0$). Equation (3) can be represented in an iso-variance map where each iso-variance curve includes all combination of cash and futures positions yielding a constant risk value. Curve V_0 in Figure 1a, for example, gives the alternative values of X and X_f necessary for (3) to sum to V_0.

In Figure 1a, the horizontal axis shows the cash position (X), and the vertical axis indicates the futures (X_f). Market positions can be purely speculative, purely hedging, or some combination of the two. All commitments established on the vertical axis are purely short speculative positions; those on the horizontal axis involve no futures position. Any point lying between the cash position axis and the 100 percent hedging line (the 45° line) repre-

[2] It is assumed that all costs (C, C_f) are linearly related to the quantity variables (X, X_f). Total revenues and cost vary in equations (1) and (2) according to the type of position. If $X>0$ and $X_f>0$, total revenue is $XP_{t+k}+X_fF_t$; but if $X_f<0$, it is $XP_{t+k}-X_fF_{t+k}$. Similarly, when $X<0$ and $X_f<0$, total revenue is $-XP_t'-X_fF_{t+k}$; but if $X_f>0$, it is $-XP_t'+X_fF_t$.

[3] McKinnon states that output at harvest time can be viewed at planting time as a random variable [5, p. 846]. This would imply that at period t the transformed X of period $t+k$ would be viewed as a random variable. Transformation risk in our framework may exist through changes in quality and weights of the initial cash stock (feeder cattle). We have assumed that quality and weight risk are reflected directly in the prices received. Price risks then absorb differences due to variations in quality and weights. We have assumed that remaining transformation risks are negligible; i.e., the same number of X units of input in period t yields the equivalent number of output units in $t+k$.

Transformation risk varies with the commodity considered, hence one extension of our framework would be to introduce a completely random transformation effect.

[4] Variances of (3) are defined to be conditional probabilities only if the prices of period t and $t+k$ are not independent. See [1, 3, 4, and 9] for useful discussions of risk-measurement criteria.

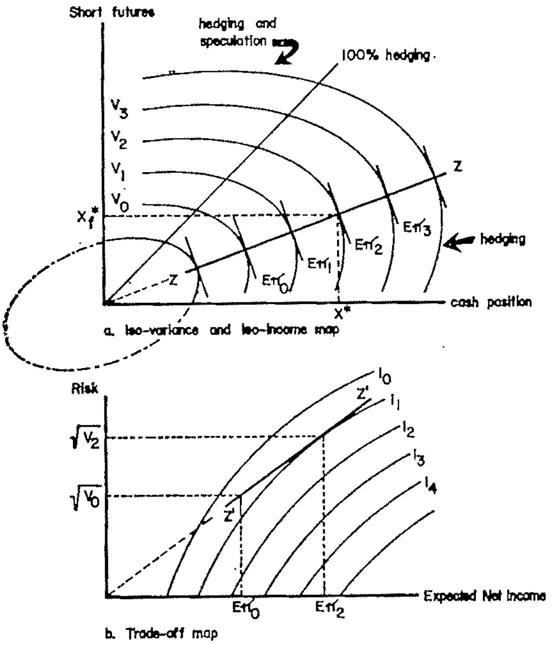

Figure 1. Risk, income, and trade-off maps when hedging is potentially profitable

sents a cash position with a short hedge, and this hedge is less than the cash position. All points lying on the 45° line represent 100 percent hedges, and points to left of this line correspond to a combination of hedging and speculation.

Expected net income equations (iso-net incomes) can be drawn over the iso-variance map as shown in Figure 1a. In this quadrant, $X \geq 0$ and $X_f \geq 0$ and the position of each iso-net income line depends on the magnitudes of X and X_f. For example, line $E\pi_0$ defines combinations of X and X_f (given $X \geq 0$ and $X_f \geq 0$) necessary for equation (1) to sum to $E\pi_0$.

The decision maker's iso-variance map is assumed constant, but his iso-net income map will vary according to his price expectations. Specifically, the slope of $E\pi_i$ will change according to the expectations in equation (1). If the decision maker's expectations are such that $\{E[F_t - F_{t+k}] - C_f\} = 0$, then the expected net income is independent of the amount of futures. In this instance, iso-net income lines would be drawn parallel to the vertical axis in Figure 1a. Probably a more realistic alternative is when the expected net returns from futures activities are greater than zero; i.e., $\{E[F_t - F_{t+k}] - C_f\} > 0$. Here expected net income is not independent of the hedging level; hence, hedging may be used, not only for its *risk-shifting capacity*, but also for its *profit potential*. The iso-net income lines may have a slope like that shown in Figure 1a. The greater (smaller) the expected futures return, the smaller (larger) will be the slope of each iso-net income line.

A decision maker will for each iso-net income choose a level of short futures that will minimize his iso-variance. Graphically, this minimum point is where an iso-net income ($E\pi_i$) is tangent to an iso-variance curve (V_i).

The combination of all possible tangency points gives the line ZZ of Figure 1a, and this tangency locus ***must be a linear*** projection from the origin of the iso-variance map since the iso-variance function used is an ellipse. All coordinates of ZZ can be plotted on a trade-off map between expected net income and risk, thus giving the locus $Z'Z'$ of Figure 1b. Any combination along $Z'Z'$ can be chosen, but the rational decision maker maximizes his utility under the constrained conditions by selecting the point that places him on his highest indifference curve. In the example from Figures 1a and 1b, $E\pi_2$ and V_2 give the constrained maximum utility. Referring back to the iso-variance map, the combination of $E\pi_2$ and V_2 indicates that X_f^* is the optimal short hedge and that X^* is the optimal cash position. Optimization has resulted in a futures position for which the cash market position was not completely hedged. If a 100 percent hedging rule were applied, the decision maker either would have to accept a higher level of risk to maintain the same expected income or reduce his output and expected income to maintain the same level of risk.

In Figure 1a the decision maker establishes a short hedge position at a higher level than if his expected net income were independent of hedging. Indeed, price expectations may be such that the decision maker chooses his optimal position to the left of the 100 percent hedging line (e.g., the tangency locus ZZ rotated counterclockwise). The futures position is then a mixture of hedging and speculation. If this should happen, and the futures position is limited to 100 percent hedging, the firm would find it necessary to raise output to maintain its expected income and risk levels. A smaller increase would be needed to keep risk at the same level, but a larger increment in output as well as a higher level of risk would be required to maintain expected income. If output were held constant, risk would decrease, but at the cost of a reduction in expected net income.

Determination of the optimal market position for the long hedger

A long hedge (buying futures) can occur only if a short cash position has been assumed in period t. The market participant has established some deferred-delivery contractual agreement at price P_t' in period t for delivery in $t+k$ and he expects to purchase the commodity in period $t+k$. Evaluation of deferred-delivery contracting and long hedging applies to those market participants not directly involved in the production process at the initial period t.

Equation (2) expresses the relevant net income for these situations ($X<0$). For example, P_t' may be the contracted price of live beef to be delivered in period $t+k$. Alternatively, P_t' may represent the contracted value of an animal unit after processing. In both instances, the cash selling price of output has been established but the purchase price is subject to variations. Income equation (2), along with the appropriate risk function, can be used to determine the optimal market positions. Only the cash and futures prices of period $t+k$ are unknown in equation (2); therefore, the variance of (2) can be written as:

$$(4)\quad \mathrm{Var}\,(\pi') = X^2\sigma_{p'}^2 + X_f^2\sigma_f^2 - 2XX_f\rho'\sigma_{p'}\sigma_f$$

where

$$\sigma_{p'}^2 = \mathrm{Var}\,(P_{t+k} - P_t') = \mathrm{Var}\,(P_{t+k} \mid P_t')^5$$

$$\rho' = \sigma_{p'f}/\sigma_{p'}\sigma_f$$

$$= \text{correlation between } (P_{t+k} - P_t') \text{ and } (F_{t+k} - F_t).$$

The optimal market position follows in the same manner as the procedure for determining cash and short hedging positions. The iso-variance and iso-net income maps are drawn in Figure 2a. The third quadrant is the relevant one since $X<0$ and $X_f<0$ when a deferred-delivery position exists and a long hedge is established. Movements from V_0 to V_4 and from $E\pi_0$ and $E\pi_4$ illustrate increases in iso-variance and iso-net income.

If a decision maker can establish a deferred-delivery sale in period t and anticipates a cash purchase in period $t+k$, then his optimal futures position must be considered simultaneously with his optimal cash market decision. For each expected net income level, the decision maker will minimize his risk; i.e., he will choose that position where the iso-net income is just tangent to an iso-variance. Again, the mechanism for expressing utility for the decision maker is through the trade-off map, Figure 2b. Effects of nonoptimal 100 percent hedging described earlier also exist in this case.

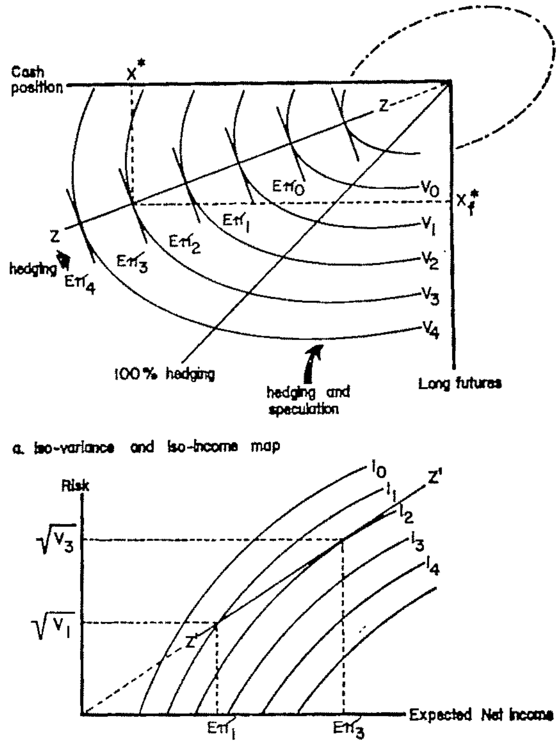

Figure 2. Risk, income, and trade-off maps for long hedges

The case depicted in Figure 2a occurs when the decision maker expects the futures price in $t+k$ to exceed the futures price and average cost of futures transactions in period t. Hence, given that $\{E[F_{t+k}-F_t]-C_f\}>0$, not only can long hedging shift some risk, but also it can increase expected incomes. As this difference approaches zero, the slope of the iso-net income lines approaches infinity; i.e., $E\pi_i$ becomes parallel to the X_f axis. The tangency locus ZZ retains the same meaning as before. All possible combinations of risk and expected net income giving the minimum variance are then plotted over the trade-off map of Figure 2b. The tangency point between $Z'Z'$ and an indifference curve give that combination of risk and expected net income leading to the optimal market position. The coordinates of this tangency ($E\pi_3$, V_3) then indicate the optimal

[5] Variances σ_p^2 and $\sigma_{p'}^2$ are identical if P_{t+k} is independent of P_t and P_t'. In this case, equations (3) and (4) are identical; otherwise, they are not the same.

long futures X_f^* and cash position X^* of Figure 2a. Through the choice of X_f^* and X^*, the decision maker has minimized his risk for a given expected net income and maximized his utility, given all other constraints.

Transition from hedging to pure speculation

Price expectations could be such that futures positions other than a hedge or a hedge combined with speculation should be established. For example, in (1) if $\{E[P_{t+k}-P_t]>C\}$, a cash holding $(X>0)$ should occur. But if expected futures price movements give $\{E[F_t-F_{t+k}]<C_f\}$, the short futures position would *not* be potentially profitable. Similarly, for the contracted cash market position $(X<0)$; if $\{E[F_{t+k}-F_t]<C_f\}$, the long position would *not* be profitable. Hence, when price expectations are such that *holding cash* and *long futures* or *forward cash* and *short futures* exist, the futures position is defined as *pure speculation*. As seen earlier, speculation in the futures market existed when the optimal futures position (short or long) exceeded the 100 percent hedging level. Now we identify a second type of speculation which occurs when the established futures position does not provide hedging possibilities in conjunction with the cash market position.[6]

Figure 3a illustrates a transition from a hedging to a purely speculative futures position. The original short position for the expected net income occurred at the tangency T, thus minimizing the risk for the given iso-net income. As expectations change, the slope of the relevant iso-net income also changes. At some point the decision maker may view the movement of futures prices to be such that $\{E[F_t-F_{t+k}]<C_f\}$. Iso-net income $E\pi_2'$ follows directly from this change in expectation. Although expected futures prices are now such that a loss is expected to occur with a short position, this point will still be chosen (tangency T'). The decision maker will choose a short futures position that minimizes risk, even though a small loss is expected from the short contract (selling futures). The decision maker is said to be paying some premium of minimizing risk.

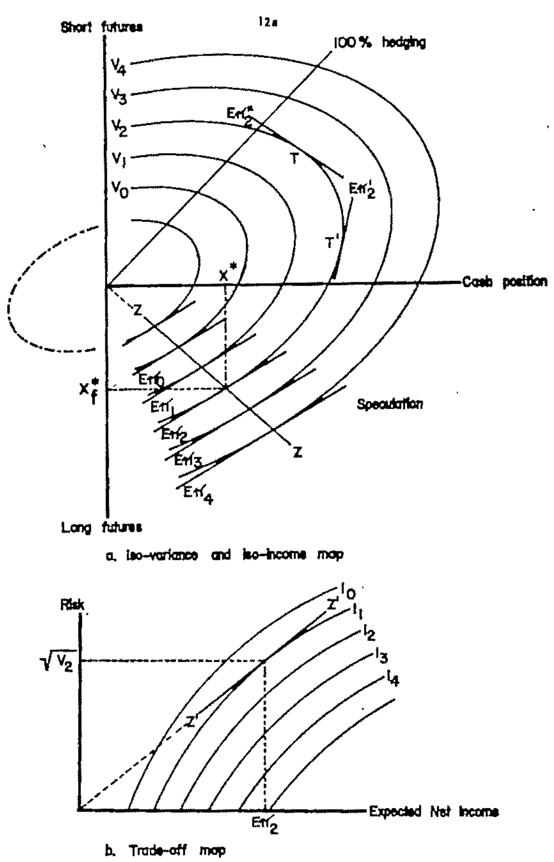

Figure 3. Transition from hedging to pure speculation

As the decision maker's expectations change, his market positions change accordingly. Given that the difference in futures price for period $t+k$ and futures at period t is expected to be large, the decision maker may become a market speculator. This would mean that, in Figure 3a, the iso-net income lines are tangent to the iso-variances only in the lower right quadrant (e.g., tangency locus ZZ rotates clockwise). The highest indifference curve attainable, given the tangency locus of Figure 3b then shows that combination of expected net income and risk $(E\pi_2, V_2)$ leading to the optimal speculative level $X_f^*(X_f<0)$ and cash position $X^*(X>0)$. Any hedging position would reduce utility, given the firm's set of expectations.

A comparable speculative position is that of deferred-delivery contracts and short futures. The decision maker views cash price movements as advantageous for a deferred-delivery position. Yet he also views the expected futures prices to be such that a short position is desirable. In period t futures are sold, and in $t+k$

[6] Both types of speculation are defined for producers and marketing firms with positions in both the cash and futures markets. Another group of market participants, called *speculators*, could be discussed. The optimal position for this group always lies on the vertical axis (short or long futures) of the iso-variance and iso-net income map.

all positions are terminated through offsetting purchases. This position could be illustrated graphically by extending the iso-variances of Figure 2a into the upper left quadrant and then determining the tangency locus, as in Figure 3.

Conclusions and Implications

A set of price expectations, a probability distribution for this set, and a preference function for risk aversion have provided the essential elements for the futures model developed in this article. Within this framework optimal futures and cash market positions were established for producers and marketing agencies. For the primary producer buying feeder cattle, the optimal cash market position was derived simultaneously with the optimal futures position. Processors, dealers, and other marketing agencies can utilize futures as hedges against contracted and anticipated purchases of live animals. The ratio of futures to cash positions could be (a) less than one (less than 100 percent hedging), (b) equal to one (100 percent hedging), or (c) greater than one (hedging and speculation). In addition, cash market participants can be pure speculators when their expectations warrant such positions.

Optimization yielding X^* and X_f^* suggests further considerations not discussed in this paper. The optimal level of X has been established, yet X may take many different forms. Feeder cattle can be purchased at many weight ranges, each requiring different transformation periods. Optimal timing of futures positions have been ignored. For example, we have derived the optimal X_f; yet for beef futures there are six possible contracts that could be used. Also, empirical determination of the assumed density functions often is difficult.

Costs of inputs were assumed given for the market participants who have cash positions in period t. Without instantaneous product transformation, costs may be uncertain. The theory of long hedging could be applied to the uncertainties of input prices for participants who make cash market sales commitments (e.g., the beef feeder). Hedges in both the input and output markets require two distinct futures markets. The processor can hedge inputs through live beef futures, but his outputs would have to be hedged in a futures market for beef carcasses. A beef feeder who completely hedges both his inputs and outputs and has expectations of zero gain or loss in the futures markets could be compared to a feedlot operator feeding cattle on contract. Both sell a service at a fixed price. Both give up the possibility of higher income to avoid risk.

The discussion has been limited to decision making in the cash and futures markets. However, a decision maker could establish many of the hedging positions through forward contracting outside of an organized market. A producer could sell forward directly to a buyer, thus establishing both the selling and buying prices between two decision makers. If both futures markets and forward contracting are feasible, a firm must decide which alternative to use. Most futures markets are characterized by ease of transactions, high liquidity, and security. Forward contracting may not provide these essential elements for successful hedging; hence, direct forward commitments may introduce new risks through an effort to minimize price risks. On the other hand, through forward contracting the decision makers can specify terms most advantageous to the two participating parties, while futures must be traded in specified and rigidly enforced contracts. Such futures contracts are designed to meet a broad spectrum of trading needs; hence, it may not be the optimal contract for any one decision maker. We have not provided formal decision criteria for evaluating these two hedging alternatives. Their similarities and differences have been discussed, but some extreme assumptions would be required to compare them in the model presented [9].

The model extends considerably the analysis of the relation between market output decisions and futures positions. Hedging and speculation are given precise meanings and are logically related to the behavior of both buyers and sellers of a commodity traded on a futures market. However, the implications of the micro model for aggregate market determination of price, output, and profits of buyers and sellers remain to be explored.

Formulating Beef Rations for Improved Performance Under Environmental Stress*

RAY F. BROKKEN

Beef ration heat increment level (energy lost in ruminant fermentation and nutrient metabolism) relative to net energy has important implications for efficient beef production under heat or chill stress. This paper presents (1) an efficient model for use of the Lofgreen-Garrett net energy system in ration formulation; (2) a model, incorporating the Lofgreen-Garrett net energy system, for varying heat increment relative to net energy in beef ration formulation; and (3) a simplified framework for ascertaining potential animal performance differences caused by differences in relative heat increment under assumed stress conditions. Differences illustrated are substantial.

LOFGREEN AND GARRETT [7, 8] have proposed a system for expressing net energy requirements and feed values for growing and finishing beef cattle. Judging from reports in industry and trade journals, this system is an important innovation in feed evaluation and ration formulation in the fed beef industry.

However, the system is complicated from the standpoint of programming least-cost rations because the total net energy value of any particular ingredient changes with the level of total energy intake. Their system separates requirements for maintenance from that for body weight gain and gives different feed energy values for feed used for these two functions. Feed energy is applied to body weight gain only if the total net energy intake is in excess of that required for maintenance.

This system reflects requirements and feed energy values in environments of *thermal neutrality*. However, in weather conditions where heat stress or chill stress becomes a problem, a third energy fraction, *heat increment*, becomes a factor in determining the rates of substitution among feedstuffs. Heat increment, which occurs concomitantly with net energy, is the difference between metabolizable energy and net energy. In chill stress there is a diversion of energy otherwise available for gain to heat production for maintenance of body temperature. Under heat stress two problems related to the level of heat increment may occur: (1) Any burdensome heat production will be expurgated by diverting energy to this purpose from that which is otherwise useful for body weight gain. (2) Perhaps more significant, because of reduced appetite, feed-intake is reduced. Data indicate that the heat increment relative to net energy for maintenance or to net energy for gain varies widely among feedstuffs [2, 14]. Therefore, a substantial variation in heat increment for any given level of net energy should be obtainable.

The purpose of this paper is to present some concepts and models for formulating beef rations for efficient production under different environmental circumstances.

Following a section giving more detailed definitions and background, a three-equation energy system is presented which incorporates the two equations of the Lofgreen-Garrett net energy system. Two linear programming models are then presented, one for dealing with the Lofgreen-Garrett system and one for obtaining variable levels of heat increment. The differences in heat increment obtainable are illustrated with ration solutions for an animal of a certain weight with two assumed rates of gain. A simplified framework for assessing the differences in animal performance with rations containing different levels of heat increment under assumed environmental conditions is then developed; and finally, an assessment is made of potential economic consequences.

Definitions and Background

Net energy is a measure of the food energy actually used by the animal after energy losses in digestion and metabolism have been subtracted from *gross energy of ingested feed* (GE_i).[1] Since the relative losses incurred in digestion

* The author is indebted to Richard E. Vaile, Gene Nelson, Dale Waldo, and two anonymous reviewers for helpful comments; and for educational discussions and references, to Paul W. Moe, W. N. Garrett, D. C. Church, R. A. Ralston and Peter R. Cheeke.

RAY F. BROKKEN *is an agricultural economist with the Farm Production Economics Division, Economic Research Service, USDA.*

[1] Terms in parentheses are standard notation in animal nutrition and are used throughout this paper. For a more thorough discussion and definition of biological energy terms, the reader should consult [2] and [15].

and metabolism vary among feedstuffs, net energy is the most appropriate energy basis for substituting one feedstuff for another in ration formulation in the absence of heat or chill stress.

Losses in digestion and metabolism occur in the form of energy in undigested feed of the feces, *fecal energy* (FE); *urinary energy* (UE); combustible gases from fermentation of the ration, *gaseous products of digestion* (GPD); and heat losses in the form of the heat of fermentation and the heat of nutrient metabolism, which taken together are *heat increment* (HI).

After all of these losses are subtracted, that which is left is *net energy for maintenance* (NE_m), which is expended as heat; and *net energy for production* (NE_p), which is mostly stored in tissues as *net energy of body weight gain* (NE_g) and in wool, feathers, etc., or in products (milk, eggs, fetus).

Obviously, direct determinations of the NE_m and NE_g content of the various feedstuffs is complicated and tedious. For that reason, it is often expedient to use less detailed indicators of relative feed values: (1) *digestible energy* (DE), which is the difference between gross energy and fecal energy, $DE=GE_i-FE$; or (2) *metabolizable energy* (ME), $ME=DE-UE-GPD$ and $ME=HI+NE_m+NE_p$.

Total heat production (HP) is the part of metabolizable energy which is not recoverable in the form of energy stored in the body weight gain. HP includes NE_m, HI, and energy diverted from NE_g to *heat to keep the body warm* (HBW) in chill stress or to *heat to keep the body cool* (HBC) in heat stress. The animal's *critical temperature* occurs when HI is fully utilized and HBW commences. If the level of feeding is so low that no NE_g is available, the HBW comes from body reserves (it loses weight). The point of *hyperthermal rise* occurs when the body temperature commences to rise. HBC is then required to expurgate the burdensome HI. The temperature zone between the critical temperature and the point of hyperthermal rise is called the *zone of thermal neutrality*. This zone can be extended over a wider temperature range by developing rations with more HI for cold weather and less HI for hot weather.

Strict additivity in the energy equations is valid only to the extent that the overall nutrient balance is maintained. That is, the rate of substitution of one combination of ingredients for another combination of ingredients is linear in energy if the same deficiencies in other nutrients (protein, minerals, vitamins, etc.) are exactly maintained. Maynard and Loosli [9, sec. 11.16] state, "Deficiencies of phosphorus, riboflavin and certain other minerals and vitamins tend to increase the heat increment of a ration. In fact, there is evidence that, other things being equal, if the ration is unbalanced with respect to any nutrient in terms of physiological needs the wastage of heat tends to be greater accordingly." This means that the net energy value of the ration would be smaller accordingly. Linearity in the context of constrained nutrient balance does not contradict studies showing nonlinear substitution between two feedstuffs that are different in overall nutrient composition.

There may be a major exception to linearity in the case of fat; see Moody et al [12]. Again quoting from Maynard and Loosli [9, sec. 11.16]: ". . . a greater than expected value of fat as a source of energy can be explained on the basis that, with equicaloric diets, increasing the fat component decreases the heat increment." This suggests that some optimum level of fat should be specified in recommended nutrient requirements, as is done with protein. The level of protein in equicaloric diets also has a marked effect on the level of HI, and consequently the NE_m and NE_g values, with the HI decreasing with increases in protein levels up to the optimum protein levels and then increasing [9].

A Three-Equation Energy System

The system consists of an equation for each of three different energy fractions: (1) NE_m, (2) NE_g, and (3) ME.

$$(1)\qquad \alpha \sum_j a_{1j}X_j = AW^{.75}$$

$$(2)\qquad (1-\alpha)\sum a_{2j}X_j = (Bg + Cg^2)W^{.75}$$

$$(3)\qquad \sum a_{3j}X_j = ME$$

where α is the proportion of feed required for maintenance; a_{1j}, a_{2j}, and a_{3j} are, respectively, the NE_m, NE_g, and ME values of the jth feed ingredient; X_j is the quantity of the jth feed consumed; $W^{.75}$ is the *metabolic weight* of an animal where W is body weight in kg.; and g is gain in kg. per day. The right-hand sides represent energy intake in Mcal. per day. Lofgreen and Garrett [7] give the following estimates for parameters of equations (1) and (2): for steers, $B=0.05372$, $C=0.00684$; for heifers, $B=0.05603$, $C=0.01265$; for steers and heifers, $A=0.077$. In equation (3), ME is the level of metabolizable energy.

Any level of ME resulting from optimizing with respect to equations (1) and (2) is accept-

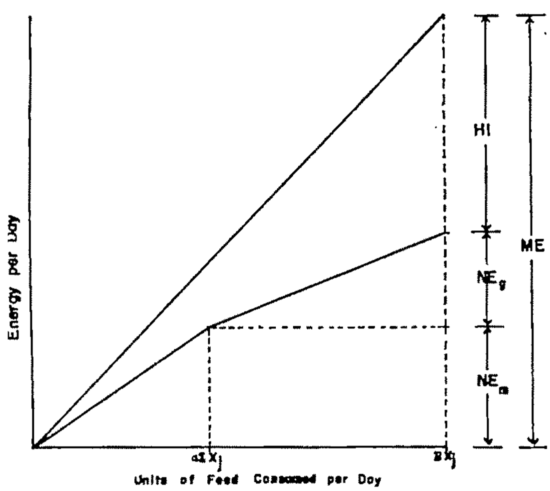

Figure 1. The relationship of three energy fractions to feed consumed per day

able in an environment of thermal neutrality. For chill stress, ME can be made larger; for heat stress, smaller. Hence, $HI = ME - NE_m - NE_g$ is indirectly varied. A graphic representation of the system is shown in Figure 1.

Linear Programming Models

The difficulty in linear programming with the Lofgreen-Garrett system, as shown in equations (1) and (2), is that both α and X_j are unknown. Since each ingredient must be multiplied by α in equation (1) and by $(1-\alpha)$ in equation (2) the system is not additive in the energy equations. However, a simple, efficient linear programming model can be developed with a few transformations.

Divide both sides of equations (1) and (2) by α and create K right-hand sides for each of $k=1, 2, \cdots, K$ possible values of α_k:

$$(5) \qquad \sum_j a_{1j}X_j = NE_m/\alpha_k$$

$$(6) \qquad \sum_j a_{2j}X_j = NE_g/(1-\alpha_k)$$

where $NE_m = AW^{.75}$ and $NE_g = (Bg + Cg^2)W^{.75}$.

Equations (5) and (6) can be easily handled in a straightforward linear programming with any specification of the parameters and any specific value of α_k. An efficient model must incorporate these right-hand sides as activities and select the optimum level of α directly in one solution. Model I is efficient in this respect.

Model I

Only the objective functions and equations dealing with the net energy and dry matter intake of the diet problem are discussed. Equations for the remaining nutrients form a simple linear system.

$$(7.1) \qquad \text{Minimize} \sum C_jX_j$$

subject to:

$$(7.2) \qquad \sum B_k = 1$$

$$(7.3) \qquad \sum a_{1j}X_j - \sum b_{1k}B_k = 0$$

$$(7.4) \qquad \sum a_{2j}X_j - \sum b_{2k}B_k = 0$$

$$\vdots$$

$$(7.m) \qquad \sum a_{mj}X_j - \sum b_{mk}B_k \leq 0$$

also

$$X_j, B_k \geq 0 \quad (j=1, \cdots, n, k=1, 2, \cdots, K)$$

where C_j is the cost per unit of the jth ingredient; X_j is the quantity of the jth ingredient, a_{1j}, a_{2j}, and a_{mj} are respectively the NE_m, NE_g, and dry matter coefficients of the jth ingredient; $b_{1k} = NE_m/\alpha_k$; $b_{2k} = NE_g/(1-\alpha)$; b_{mk} is the dry matter intake level appropriate for the specifications of requirements for NE_m and NE_g;[2] and B_k is a weighting factor for α_k or more directly for b_{1k} and b_{2k}.

Intervals of $\alpha_{k+1} - \alpha_k = .01$ are used. Obviously the optimum level of α must fall in the range $0 < \alpha \leq 1$, but a much narrower range can be specified.

In equations (5) and (6) a_{1j} can equal a_{2j} $(j=1, \cdots, n)$ only if $NE_m/\alpha = NE_g/(1-\alpha)$, in which case $\alpha = NE_m/NE_m + NE_g$. Since $a_{1j} > a_{2j}$ for all j; $\alpha < NE_m/NE_m + NE_g$. Alternatively, the proportion of feed expended for maintenance, α, is at a minimum if all $a_{1j} = a_{1*}$, where a_{1*} is the largest NE_m coefficient of all ingredients. The complement, $1-\alpha$, reaches a minimum if all $a_{2j} = a_{2*}$, where a_{2*} is the largest NE_g coefficient of all j ingredients.

Hence,

$$(8) \qquad \frac{NE_m}{a_{1*}b_m} < \alpha < 1 - \frac{NE_g}{a_{2*}b_m}$$

where b_m is the constraint level of daily dry matter intake. An initial upper limit on α is

[2] The dry matter constraint is a very important factor in determining the optimum ration. For application of this model, dry matter intake levels suggested in the NRC guidelines for beef cattle [13] were used. The NRC states that feed consumption is affected by the age and condition of an animal. Further, it is known that the level of dry matter intake is a function of the energy concentration of feed [1, 3]; however, no such functions for beef cattle are published.

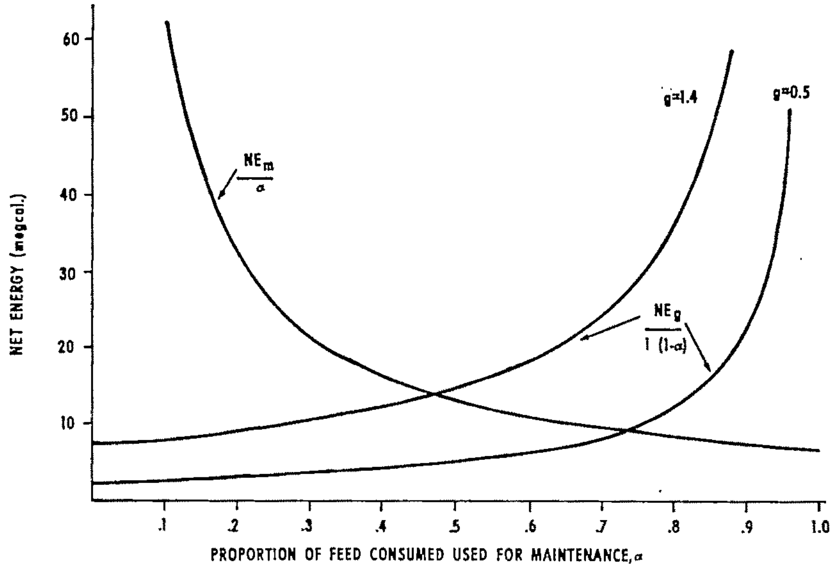

Figure 2. NE_m/α **and** $NE_g/(1-\alpha)$ **for all values of** α **(365 kg. steer, two rates of gain)**

placed at the smaller of $1-(NE_g/a_{2*}(b_m))$ or $NE_m/(NE_m+NE_g)$.[3]

Figure 2 shows the relationship of the level of α to NE_m/α and $NE_g/(1-\alpha)$. The error due to interpolation between two points on the NE_m/α curve, say between points at α_k and α_{k+p}, is expressed by (9):

$$\frac{[(B_k(NE_m/\alpha_k) + B_{k+p}(NE_m/\alpha_{k+p})] - [NE_m/(B_k\alpha_k + B_{k+p}\alpha_{k+p})]}{NE_m/(B_k\alpha_k + B_{k+p}\alpha_{k+p})} \tag{9}$$

Hence, the smaller the difference $\alpha_{k+p}-\alpha_k$, the smaller the error due to interpolation. If $\alpha_{k+1}-\alpha_k$ is very small, the solution needs to contain B_k vectors for only two adjacent values of k in order to assure that errors due to interpolation are a minimum.

Since the value of the objective function as a function of α is convex from below, not more than two B_k vectors enter the solution and more than one enters only with adjacent values of k. Hence, no special procedure such as integer programming or separable programming is required to achieve a minimum level of error due to interpolation. With the intervals $\alpha_{k+1}-\alpha_k=.01$, solution errors in NE_m/α_k due to interpolation have been in the order of 0.04 percent—virtually zero.

[3] After working with a few solutions, much narrower limits can be established. For example, if the optimum level for a particular problem is between α_r and α_{r+1}, a range of $\alpha_r-.02$ and $\alpha_r+.03$ should apply to nearly all future problems of the same specifications for daily gain. It is a simple matter to modify the problem to include a narrower or wider range on α.

In applying this model with IBM/MPS/360 a single matrix was used containing the ingredient variables and B_k variables for several weight classes and rates of gain for both steers and heifers. These variables are efficiently created on the computer, using the Lofgreen-Garrett net energy functions and arrays of data for α and for other nutrient requirements.

A solution for a particular sex, weight, and rate of gain is obtained by partitioning the matrix, with appropriate instructions to include only nutrient specification relevant to the type of animal under consideration. A sequence of solutions for different rates of gain is easily obtained for a cost of approximately $2.00 per solution.[4] This cost is sufficiently small to warrant considerable exploration of optimum rations under a variety of dietary specifications.

Model II

To formulate rations with varying levels of heat increment, a constraint for metabolizable energy is added to Model I. Constraint (7.5a) is used for reducing HI or constraint (7.5b) for increasing HI:

[4] J. A. McDonough has recently developed a very ingenious procedure for use with the Lofgreen-Garrett net energy system which obtains the least cost of gain ration directly [10].

[a] αSI stands for α selection imperative.
[b] Coefficients under B_k on row 7.3 are $-6.43/\alpha$ for $\alpha = 0.31, 0.32, \cdots, 0.46$.
[c] Coefficients under the B_k on row 7.4 are $-7.28/(1-\alpha)$ for $(1-\alpha) = 0.69, 0.68, \cdots, 0.54$.
[d] For finding the maximum HI, the constraint 7.5b is used.

$$\text{(7.5a)} \qquad \sum a_{3j} X_j \leq M - 1(\theta)$$

$$\text{(7.5b)} \qquad \sum a_{3j} X_j \geq 0 + 1(\theta)$$

where a_{3j} is the ME coefficient for the jth ingredient; M is an arbitrary quantity at least as large as the ME value occurring in solutions of Model I where ME is not a binding constraint; and θ is a parameter that is varied.

When θ is a maximum in constraint (7.5a), the level of $ME = M - \theta$ is a minimum and $HI = ME - NE_m - NE_g$ is also a minimum. In constraint (7.5b) $ME = \theta$ and maximum θ gives a maximum HI for fixed levels of NE_m and NE_g.

Solutions of Model II with constraint (7.5a) for reducing HI levels is well behaved in the sense that only a single B_k vector or two adjacent B_k vectors enter the solution. However, the problem is not well behaved in obtaining increasing levels of HI with constraint (7.5b).

Solutions with θ a maximum in constraint (7.5b) always give solutions with vectors B_1, $B_K > 0$; hence, the error due to interpolation may be large.[5] A practical procedure for limiting solution errors caused by nonadjacent B_k variables is to place a narrow limit on the range of k: (1) Solve Model II with constraint (7.5a); (2) from the minimum HI solution with adjacent vectors B_r and B_{r+1}, use r as the upper value of k; (3) exclude all B_k vectors except B_{r-2}, B_{r-1}, and B_r; (4) solve Model II with constraint (7.5b) for increasing levels of HI. An efficient integer program limiting the solution to a single B_k vector might be preferable to the above four-step procedure if the ability to vary θ is not given up.

[5] The maximum error in constraint (7.3) resulting from interpolation between the extreme points, NE_m/α_1 and NE_m/α_{16}, is 3.8 percent. This value is calculated with $B_1 = B_{16} = 0.5$, $NE_m = 6.43$, $\alpha_1 = 0.31$, and $\alpha_{16} = 0.46$.

A tableau representation of Model II with constraint (7.5a) is shown in Table 1.

Solutions

Six blends (rations) are presented to illustrate the differences in HI obtainable and the interpretation of potential differences in animal performance under assumed conditions of environmental stress. The blends designated 1 and 2 refer to (1) a steer weighing 365 kg. expected to gain 1.4 kg. per day; and (2) a steer of the same weight expected to gain 1.3 kg. per day. Dietary specifications a, b, and c, respectively, refer to blends with maximum, minimum, and intermediate levels of HI.

The daily dietary specifications included the following, which were the same for ration sets 1 and 2: fiber, 8 percent minimum; ether extract, 8 percent maximum; urea, 1 percent maximum; molasses, 10 percent maximum; beet pulp, 25 percent maximum; dry matter, 9.12 kg. maximum (100 percent dry basis); and NE_m, 6.43 Mcal. For set 1, NE_g is 7.28 Mcal. per day and digestible protein is 0.79 kg. minimum per day; for set 2, NE_g is 6.69 Mcal. per day and digestible protein is 0.75 kg. minimum per day [6, 7].

The composition of ingredients is shown in Table 2 and the composition of the six blends in Table 3.

The actual feed intake due to ad libitum consumption of these blends is not known. However, if consumption in the amounts shown by the solutions occurs, the expected gains will take place under an environment of thermal neutrality (assuming the gain parameters of Lofgreen and Garrett apply). Comparison of animal performance among the six blends under thermal neutrality is shown in Table 4. Comparison of the six blends under conditions of

environmental stress is shown in Table 5 for heat stress and in Table 6 for chill stress. Of the six blends, blend 2a has the highest level of HI relative to NE_g and blend 1b has the lowest level of HI relative to NE_g.

Environmental stress is defined for heat stress as a condition in which $HBC>0$ or feed intake is reduced to avoid HBC; for chill stress, as a condition in which $HBW>0$ or feed intake is increased to avoid HBW.

Interpretation under heat stress

Assume the environment is constant over a 24-hour period and that an animal in this environment reaches its point of hyperthermal rise as its total HP reaches a rate of 16.10 Mcal. per day. Further assume that the HP from NE_m, HI, and HBC is evenly distributed over this period.

Two interpretations are offered: (1) where HI is consumed at levels burdensome to the animal and the burden, B, must be expurgated by diverting energy from NE_g to HBC; (2) where the animal avoids stress by eating less.

Let B denote the quantity of burdensome HI and let δ, a heat elimination factor, denote the

Cents per kg. gain	30.42	27.22	28.48	27.88	23.58	22.66

quantity of energy required to expurgate one unit of B. Hence, the heat generated to expurgate B is δB, which in turn is eliminated by $\delta(\delta B)$, which in turn is eliminated with the same efficiency, ad infinitum:

$$(9) \qquad HBC = B(\delta + \delta^2 + \delta^3 + \cdots)$$

This series converges to

$$(9a) \qquad HBC = \frac{B\delta}{1-\delta} \qquad \text{for } -1 < \delta < 1$$

Obviously, for the case in point, $0<\delta<1$.

The burdensome HI, B, per marginal unit of feed consumed is the difference between ME per unit of the blend, a_3, and the NE_g per unit of the blend, a_2.

HBC per unit feed consumed is just equal to a_2 when δ is equal to the ratio of NE_g per unit feed to ME per unit feed:

$$HBC = a_2 = \frac{\delta}{1-\delta}(a_3 - a_2),$$

so (a) if $\delta = a_2/a_3$, additional NE_g available for gain neither increases nor decreases with additional feed consumption; (b) if $\delta > a_2/a_3$, NE_g available for gain decreases with increased feed consumption; and (c) if $\delta < a_2/a_3$, NE_g available for gain increases with increased feed consumption.

The amount of gain sacrificed in heat expurgation, once the value of δ is established, depends on the amount of NE_g per unit of feed relative to the HI per unit of feed. The advantage under heat stress lies with rations that have high ratios of NE_g per unit HI for two reasons: first, the amount of NE_g at the point of hyperthermal rise is greater; and second, for every unit of heat that must be eliminated there is a larger amount of NE_g to be diverted.

For comparing rations with unequal levels of burdensome HI, the value of δ is set equal to the ratio a_2/a_3 of blend 1b ($\delta = 0.447$).[6] Therefore, blend 1b falls in category (a) above, and the NE_g concomitant with the burdensome HI is just sufficient for the necessary HBC. The remaining blends fall in category (b). Thus, except for blends 1b and 2b, the gains are higher in the second part of Table 4, but consumption levels are higher in the first part.

A graphical representation of the various energy fractions under heat stress for blends 2a and 1b is shown in Figure 3, first for the case where energy is diverted from NE_g to HBC and second for the case where stress is avoided by reducing the consumption to the level where no burdensome HI occurs. The numbers on the vertical axes refer to the NE_g, NE_m and ME per kg. of the blend in ascending order. Numbers on the horizontal axes refer to levels of feed consumption per day. Hence, in the upper left diagram of Figure 3 the total NE_m per day is represented by the area formed by multiplying NE_m per kg. of the feed times the kg. of feed consumed. The overall area is ME which is divided into NE_m, HI, B, NE_g, and HBC.

Under thermal neutrality, 9.12 kg. of blend

[6] This value is arbitrary and is used only to illustrate differences in HBW associated with different levels of HI relative to NE_g.

Cents per kg. gain	35.03	31.13	28.85	27.88	26.69	25.67

2a results in a gain of 1.3 kg. per day at a cost of 27.22 cents per kg. of gain. With this same level of consumption under the assumed heat stress conditions, 3.45 Mcal. of the original NE_g is diverted to HBC, leaving only 3.26 Mcal. which is enough for only 0.61 kg. gain. Had the animal instead reduced its intake to 6.98 kg., it would have entirely avoided the burdensome HI and could have gained 0.87 kg. per day, or 0.19 kg. more per day. The ingredient cost per kg. gain would have been reduced from 52.03 cents to 31.13 cents.

Similar comparisons for blend 1b show that the gain of 1.4 kg. under thermal neutrality is reduced to 1.32 kg. under the stress conditions, whether by diverting 0.51 Mcal. to HBC to eliminate the burdensome HI or by reducing consumption by 0.40 kg. to avoid the burden. The cost per kg. gain is increased from 28.4 cents under thermal neutrality to 30.44 cents in the case of heat elimination or to 28.85 cents in the case of reduced feed intake.

In reality, heat elimination may be highly efficient except under very severe heat and humidity. Hence, only small amounts of energy may be expended in HBC, with the major loss in gain and consequent loss in feed efficiency under heat stress due to reduced feed intake.

High producing animals must eat large quantities of NE_p and consequently large

quantities of the *HI* associated with it. Therefore, adjustment in rations during hot weather would be more important for a dairy cow producing at an annual rate of 7,000 kg. than for one producing at a 4,500-kg. rate. Likewise, a beef steer capable of gaining 1.7 kg. per day might benefit significantly from lowering the *HI* relative to NE_g, while no benefits would accrue to an animal capable of gaining only 1 kg. per day.

Interpretation under chill stress

Assume an environment in which an animal approaches the lower limit of its zone of thermal

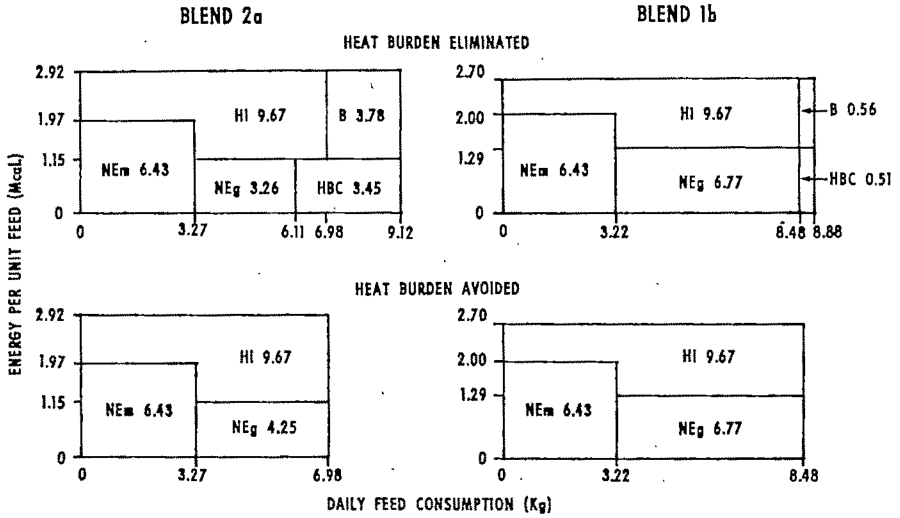

Figure 3. Energy fraction comparisons of two blends with two heat stress reactions (point of hyperthermal rise @ $HI = 9.57$ Mcal. per day and heat elimination factor, $\delta = 0.447$)

neutrality (its critical temperature) as its ration of blend 2a approaches 9.62 kg. per day. Total heat production is 20.79 Mcal. per day with a maximum HI of 14.35 Mcal. which is fully used for maintenance of body temperature. Since the $NE_m = 6.43$ Mcal. per day for all rations, discussion focuses on the magnitude of HI relative to NE_g. The NE_g level is 7.28 Mcal. or enough for 1.4 kg. gain per day. Again assume that climatic conditions and HP from NE_m, HI, and HBW are constant through time for the 24-hour period.

Three sets of comparisons are summarized in Table 6 for all six blends and in Figure 4 for blends 2a and 1b. In the first set of comparisons the intake of all six blends is set at the levels used in Table 2 for an environment of thermal neutrality. None of the rations measures up to 14.35 Mcal. of HI necessary to achieve the critical temperature. The deficit in each case is

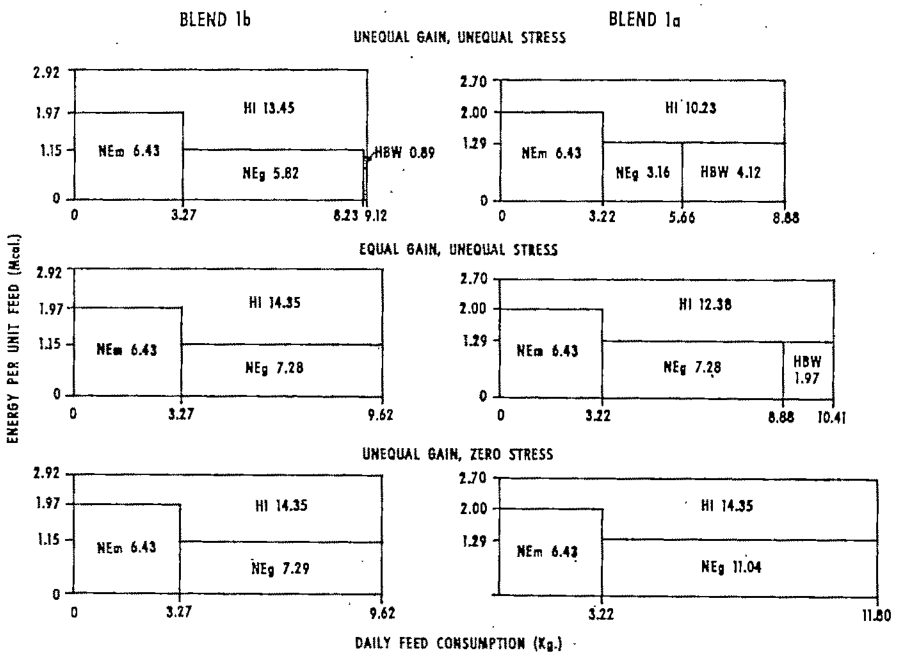

Figure 4. Energy fraction comparison of two rations with three chill stress reactions (critical temperature @ $HI = 14.35$ Mcal.)

shown as HBW, which is diverted energy otherwise usable for NE_g. The HBW is 0.89 and 4.12 Mcal., respectively, for the specified intake of blends 2a and 1b. The NE_g remaining is 5.82 and 3.16 Mcal. which is enough, respectively, for 1.15 and 0.66 kg. gain per day.

In the second set of comparisons the intake of all rations is adjusted upward to a level that secures 7.28 Mcal. of NE_g net of that transferred to HBW. This example shows that chill stress might lead to an increase in feed intake without increases in weight gain per day. In this case the animal may suffer chill stress ($HBW > 0$) as its critical temperature is reached even though gains are not effected. The economic consequences of chill stress are reduced if the animal adjusts its consumption upward to meet additional heat requirements from both HI and HBW.

The third set of comparisons shows the rations of each blend necessary for an animal to reach its critical temperature. As shown in Figure 4, blend 1b would have to be consumed in the amount of 11.8 kg. to achieve the critical temperature. The accompanying NE_g is 11.04 Mcal. for an implied gain of 1.99 kg. per day. Few, if any, 365-kg. animals can achieve such a large gain. Hence, it is very improbable that the animal will consume blend 1b in quantities large enough to achieve his critical temperature in the assumed environment.

Economic interpretation

A full assessment of the economic implications of changing HI vis-à-vis environmental stress is not attempted in this paper, which is more limited in scope.

The introduction of an additional binding constraint always results in cost equal to or greater than before. Thus, blends 1c and 2c, which were obtained with no restrictions on the amount of heat increment, are much less costly than blends 1a, 2a, 1b, and 2b and would be much preferred in environments of thermal neutrality. The economic issue of concern is whether the additional cost of adjusting the blends for stress conditions is worth the advantage of the resulting improvement in performance.

Under heat stress, blends 1b and 2b are more efficient in both energy utilization and cost of gain than the other blends either when (a) diverting NE_g for HBC to eliminate the heat burden or (b) avoiding the heat burden by reducing feed intake. However, the reduction in cost could be greater or smaller under different sets of ingredient prices.

The blends presented here represent extreme cases for HI in the context of the dietary specifications made and ingredients considered. A more economical blend for heat stress conditions may be one with HI intermediate between blends 1b and 1c or between blends 2b and 2c. For example, the HI level and cost for every solution proceeding from the least-cost blend to the blends with minimum and with maximum HI are shown in Figure 5. From HI of 12.84 Mcal. for blend 2c, a reduction of HI of 1.72 Mcal. per day was secured at an increase in cost of 1.08 costs per day, or 3.7 percent per day. The reduction of 3.17 Mcal. of HI to the minimum HI in blend 2b of 9.67 Mcal. was secured for an additional cost of 6.82 cents, or 23.2 percent per day.

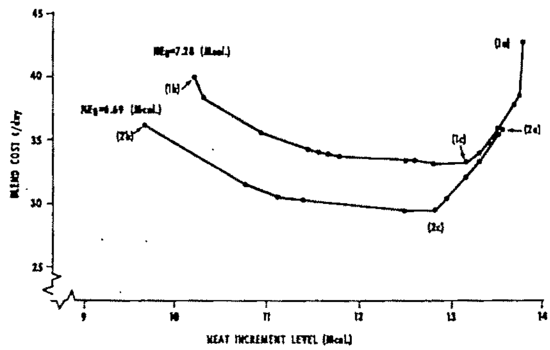

Figure 5. Blend cost vs. heat increment level for two levels of NE_g (each dot represents a solution point)

Since forages have higher relative HI than concentrates, more economical reduction in HI might be secured if it were possible, as some evidence indicates, to reduce the level of the fiber content (used in this analysis as a proxy for roughage requirements). The advantage claimed for low roughage rations and rations with inert materials substituted for roughage should be examined in light of the HI aspect of low roughage rations. If the low HI is a factor in the performance of low roughage rations, advantages may be underestimated in hot weather and overestimated in cold weather.[7]

Since the HI levels are very near the maximum obtainable levels for the least-cost blends, blends 1c and 2c are shown to have the least

[7] Using data in Table 2, the heat increment relative to NE_g, $(ME - NE_g) \div NE_g$ for concentrates varies from 0.997 for beet pulp to 1.591 for cane molasses, while for roughages this ratio varies from 1.608 for corn silage to 9.586 for barley straw.

cost per unit gain in all three sections of the chill stress comparisons in Table 6. However, there is a substantial advantage indicated for the rations with maximum HI over rations with minimum HI, and under different price ratios the advantage of increasing HI for chill stress could be large.

As stress conditions become more extreme it may be economical to modify the NE_g specifications to allow greater flexibility in changing HI. For example, the HI level relative to NE_g is higher for blend 2a than for 1a. A further reduction of the NE_g specification would yield an even higher ratio of HI per unit NE_g.

Clearly, much additional exploration is needed with (1) an expanded list of ingredients; (2) several sets of prices representative of ingredient prices in several regions of the country; (3) changes in specifications for rates of gain, required levels of roughages, and fat content; and (4) rations with HI levels intermediate between the extremes.

If changing relative HI levels in rations during periods of heat or chill stress is economic, information on the conditions under which stress occurs becomes important. Functions or distributions showing the rate at which HI occurs over time following feeding are needed. There is substantial literature describing the variables involved in environmental stress [4, 11, 12, 16, 17] and the general effects on animals during stress. Practically no quantitative information is available on the extent and duration of stress and its consequences to feed efficiency.

Summary

A theoretical framework for blending rations to improve performance of beef cattle under heat or chill stress is presented. The framework and computational procedures used involve a systematic variation of the heat increment in rations with constant amount of net energy for maintenance and net energy for gain. The heat increment of a ration is useful for maintenance of body temperature in chill stress but is burdensome and must be expurgated in heat stress.

The energy system used employs three equations, two of which are the net energy equations of the Lofgreen-Garrett net energy system. The third is for metabolizable energy. The solution requires techniques developed by the author for the Lofgreen-Garrett system, along with parametric programming on metabolizable energy so as to vary indirectly the heat increment. Two sets of three rations with the maximum, minimum, and intermediate levels of HI were obtained. Comparisons under different assumed environmental conditions indicate how much improvement in animal performance can be obtained by changing the rations when environmental stress occurs. Economic analysis indicates that the increased ration cost of adjustments in HI to meet stress conditions can be more than offset by the benefits of the resulting improvement in performance. Whether this is so depends on ingredient prices, the degree of stress, and how the animal adjusts feed intake when stress conditions occur.

The Regional Impact of Lamb Imports on Equilibrium Returns to Domestic Producers, 1967*

HOY F. CARMAN AND JAMES A. MAETZOLD

There is little agreement on producer costs and consumer benefits resulting from meat imports. This paper utilizes a spatial equilibrium model to analyze the regional impact of three levels of lamb imports on United States lamb producers and consumers. Results demonstrate regional as well as quarterly variation. Most of the variation is explained by quarterly marketing patterns, shifts in demand, changes in optimum distribution patterns, changes in levels of imports and ports of entry, and restricted ports of entry for imports.

UNITED STATES lamb producers have been voicing concern over recent increases in chilled and frozen lamb imports, products not covered by present meat quota laws.[1] Lamb imports averaged about 12.75 million pounds annually between 1964 and 1967, or approximately 2 percent of estimated U.S. lamb production. Sharp increases raised 1968 lamb imports to 23 million pounds [13, p. 22] and 1969 imports to 44 million pounds [14, p. 26]. Imports in 1969 equalled 8.6 percent of estimated U.S. lamb production.

The impact of meat imports—and more specifically, lamb imports—on returns to domestic producers is a subject on which there is little agreement. Producer groups and their representatives argue that uncontrolled lamb imports reduce domestic prices and are a factor in recent declines in domestic sheep numbers. At the other extreme, representatives of meat importers argue that, because of intensive promotion of imports and nonavailability of domestic lamb during some time periods, the demand (and price) for lamb is higher than it would be without imports.[2]

Our analysis shows that imports have both costs and benefits for the receiving country, costs in the form of decreased returns to domestic producers, benefits in the form of increased supplies of meat at lower prices to consumers. Results of the analysis provide estimates of the regional costs of imports to producers as well as consumer benefits under conditions existing in 1967.[3] The analysis is performed on a quarterly basis for 20 regions in the United States. Producer costs and consumer benefits are examined for three levels of imports.

Theoretical Framework

An extension of the well-known two-region spatial equilibrium model is utilized for the analysis. Market equilibrium for the simple two-region case is illustrated in the top portion of Figure 1. Before trade, quantity q_1 was sold at price p_1 in region A and quantity q_2 was sold at price p_2 in region B. Since the difference in price $(p_1 - p_2)$ is greater than the cost of transportation, T, trade will occur; region B will ship quantity $q_3 - q_4$ to region A. This will result in new equilibrium prices p_3 in region A and p_4 in region B, the difference between the prices $(p_3 - p_4)$ being equal to the cost of transportation between the two regions.

The U.S. lamb industry is characterized by seasonality and regionality of both supply and demand. It is thus reasonable to expect the price impact of imports to vary by region because of (1) seasonal variation in the quantity of imports, (2) seasonal variation in regional lamb sales, (3) changes in optimal distribution patterns due to lamb imports, and (4) restricted ports of entry for imports. The last two points deserve clarification. Ocean transportation limits entry of lamb imports to regions with port facilities. The majority of lamb imports enter the northeastern United States, a deficit producing region; most of the remainder enters west coast ports. Major ports include Baltimore, New York, and Philadelphia.

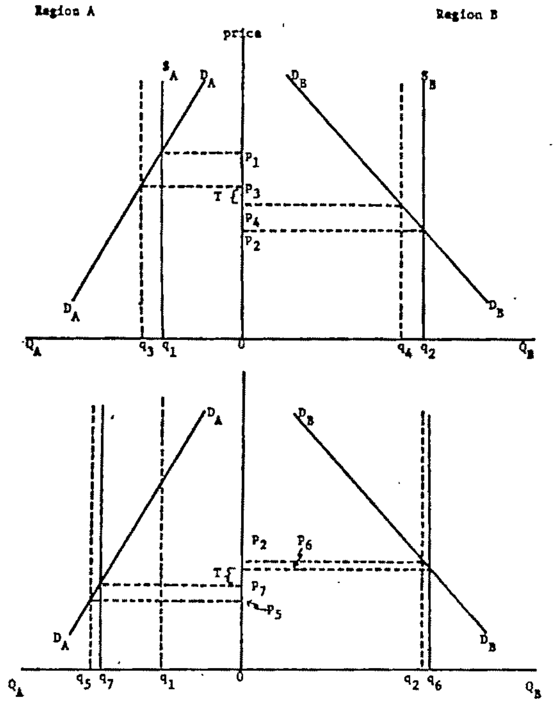

Figure 1. Competitive equilibrium between regions A and B before and after trade and after imports enter region A

Since the West Coast is an important lamb producing region, it is easy to visualize a situation in which increased imports would change western regions from a deficit to a surplus status relative to other regions. Under the assumptions of Model III this situation does occur in the second quarter, and its impact on producer prices is dramatic. The lower portion of Figure 1 illustrates the impact of imports from another country entering region A, which formerly imported from region B. The initial impact of imports equal to $q_5 - q_1$ entering region A would be to depress prices to p_5. These imports will substitute for shipments from region B, since it is no longer profitable for region B to ship to region A. Even after region B stops shipping to region A, prices in region A are lower than in region B by more than the cost of transportation. Under equilibrium conditions, region A will ship quantity $q_5 - q_7$ to region B. The new equilibrium prices, p_6 and p_7, again differ by the cost of transportation between the regions, but region A is now shipping lamb to region B. Whenever the situation just described occurs, the price impact of imports will be at least two times the transportation charge $(p_3 - p_4)$ greater in region A than in region B.

The Model

The transhipment model, a modification of the standard transportation model, is utilized for the analysis.[4] This model minimizes regional production and transfer costs for shipment of primary and intermediate goods by a sequence of points to final demand regions. Regional equilibrium of supply and demand occurs by (1) consumption of locally produced lamb, (2) importing lamb meat from other regions, (3) exporting lamb meat to other regions, and (4) importing or exporting feeder lambs for feeding. Thus, the analysis is concerned with lamb production, feeding, transportation, and consumption. The direct solution of the model provides least-cost shipment patterns for feeder lambs and lamb meat; the dual solution yields equilibrium retail and farm prices, regional price differentials, and location rents.

A quarterly analysis is performed for 20 supply and demand regions in the United States.[5] Three models analyze the distribution patterns and producer returns for lamb under various levels of imports. All models are based on estimates of 1967 regional and quarterly marketing patterns, cost of production, transportation costs, slaughter weight, and dressing percentages.[6] It is assumed that lambs are slaughtered in the region where they reach slaughter weight.[7]

Model characteristics are:

Model I—There are no lamb imports from other countries.

---

[4] For a presentation and reformulation of the transhipment model, see [5] and [4].

[5] The regional demarcation is as follows: 1, Oregon, Washington; 2, California; 3, Idaho; 4, Utah, Nevada; 5, Arizona; 6, New Mexico; 7, Colorado; 8, Wyoming; 9, Montana, North Dakota; 10, South Dakota, Nebraska; 11, Kansas, Oklahoma; 12, Texas; 13, Arkansas, Louisiana, Mississippi, Alabama, Florida, Georgia, South Carolina, North Carolina; 14, Missouri, Illinois; 15, Iowa; 16, Minnesota, Wisconsin; 17, Michigan, Indiana, Ohio; 18, Kentucky, Tennessee; 19, Virginia, West Virginia; and 20, New England States, New York, New Jersey, Delaware, Maryland, Pennsylvania.

[6] Estimating procedures and data on costs of production, transportation costs, and quarterly marketings are included in [9].

[7] One reviewer correctly pointed out that lamb slaughter capacity is limited in some regions and, in fact, not all lambs are slaughtered in the region where they reach slaughter weight. Since the purpose of this analysis is comparative rather than predictive, this limiting assumption has little effect on conclusions drawn from the study. Equilibrium results will tend slightly to underestimate total transportation costs and overestimate total producer returns.

Table 1. Estimated quarterly U. S. retail demand for carcass lamb, constrained regression, linear in logarithms, 1949–1967[a]

Time period	Constant term	Variables					R^2	d^c
		Price of lamb	Price of beef	Price of pork	Price of fryers	Income[b]

[a] For details on the estimation of these demand functions see [9]. Price elasticities are estimated subject to the constraint of the income coefficient.
[b] The income coefficient is based on 1965 cross-section data.
[c] The Durbin-Watson test indicated no serial correlation existed in the second quarter equation and was inconclusive for the other equation.
[d] Since the equation is fit in logarithms, the coefficients can be interpreted as elasticities.
[e] Values in parentheses are "t" statistics.

Model II—There are 13.146 million pounds of lamb imports from other countries.[8]

Model III—There are 26.292 million pounds of lamb imports from other countries.

The Analysis

Demand

The demand for lamb utilized in this study is the quarterly retail level demand for carcass lamb. No distinction is made between fat and fed lamb or between domestic and imported lamb.[9] Data limitations prevent an examination of the impact of promotional expenditures on the demand for lamb. Quarterly demand functions estimated by single equations linear in logarithms with per capita consumption of lamb the dependent variable, are presented in Table 1.[10] The income coefficient is based on cross-section data; thus the price and cross elasticities of demand are estimated subject to the constraint of the income coefficient. Signs on all of the coefficients except the price of pork in the third and fourth quarters were in agreement with a priori expectations. Neither of these two pork price coefficients was significantly different from zero.[11]

Income elasticities were estimated from cross-section data collected during the 1965 Food Consumption Survey [12]. Results of estimating cross-section demand equations, with quantity the dependent variable, are presented in Table 2.[12] Since data were available only for Spring, we assume that income elasticity of demand is the same for all quarters. Results appear reasonable, except for the negative income coefficient

[8] This is the product weight of 1967 lamb imports. For the analysis, this figure was converted to a 1,000-pound carcass equivalent by multiplying by a factor of .00182.

[9] These assumptions are necessary because of data limitations; see [7, p. 116]. Fat lambs, fed lambs, and imports, while substitutes, usually have separate price ranges. Part of the price difference between fat and fed lambs is reflected in the quarterly demand function, since the majority of fat lambs are sold in the second and third quarters while most fed lambs are sold in the first and fourth quarters. Fat lambs are sold directly off the ewe, four to six months after birth at approximately 90 to 110 pounds. Fed lambs are fattened two to four months in feedlots or on pasture and are sold at a weight of 90 to 115 pounds.

[10] For details on the estimation of these demand functions see [9]. Both price-dependent and quantity-dependent forms of the demand equations were estimated. The quantity-dependent form was more satisfactory, in terms of the signs and magnitudes of coefficients agreeing with a priori expectations, than the price-dependent form. The quantity-dependent form also yields direct estimates of price and cross elasticities of demand which are required in the development of regional demand functions.

[11] Results of the demand analysis utilized in this study are generally consistent with other studies. Logan and Boles found that the demand for lamb is seasonal, with quarterly demand functions showing shifts in both intercept and slope values [8, p. 1058]. Brandow found the price elasticity of demand for lamb was −2.35 at retail and −1.78 at the farm level during the 1955 to 1957 period. He also estimated the income elasticity of lamb at +.65, which was the largest value for the meats he considered [1, p. 17]. Also see [7, p. 89] and [11, pp. 85–90].

[12] For a definition of household region as utilized in the Household Food Consumption Survey, see [12].

Table 2. Cross-section demand functions for lamb, by household region, 1965[a]

Region	Constant	Income coefficient	R^2
Northeast	−4.5313	1.0826 (4.194)[b]	.66
North Central	−3.2754	.5034 (1.779)	.26
South	−3.4244	.5075 (2.030)	.31
West	−.8870	−.0787 (−.297)	.01
United States	−3.1484	.5712	.76

Source: Unpublished worksheets estimated by P. S. George in connection with his study of the demand for food [3]. (Available from G. A. King, Department of Agricultural Economics, University of California, Davis.)

[a] The coefficients are based on log functions and can thus be interpreted as income elasticities.

[b] Values in parentheses are "t" statistics.

for the West. However, as shown, it was not significantly different from zero.

Since neither price nor quantity data are considered adequate for estimating statistical demand functions separately for each region, a procedure similar to that employed by King and Schrader was utilized [6, pp. 357–362]. The constant price and cross elasticities estimated in the quarterly demand functions are utilized to derive linear approximations of regional demand. The general linear equation is

$$Q = a + b_1P + b_2I + \sum_{k=3}^{5} b_kS_k$$

where

Q = per capita consumption of lamb,
a = constant,
P = average retail price of carcass lamb in dollars per pound,
I = per capita disposable income, and
S_k = average retail prices of substitute meats in dollars per pound, $k=3$ is beef, $k=4$ is pork, and $k=5$ is fryers.

Working from the price elasticity formula,

$$Ep = \frac{\partial Q}{\partial P}\cdot\frac{\overline{Q}}{\overline{P}}$$

and since the equation is linear,

$$b_1 = \frac{\partial Q}{\partial P}$$

or

$$b_1 = Ep\,\frac{\overline{Q}}{\overline{P}}$$

and similarly for the income and substitute effects,

$$b_2 = E_I\,\frac{\overline{Q}}{\overline{I}}, \qquad b_k = E_{sk}\,\frac{\overline{Q}}{\overline{S}_k}$$

and the constant is

$$a = \overline{Q} - b_1\overline{P} - b_2\overline{I} - \sum_{k=3}^{5} b_k\overline{S}_k$$

where the bar indicates the average value for 1967.

The per capita demand for lamb in region i for quarter j can be expressed as

$$Q_{ij} = a_j + b_{1j}P_{ij} + b_{2j}I_{ij} + \sum_{k=3}^{5} b_{kj}S_{kij}.$$

Since the price and quantity of substitute meats are taken as given for the quarter involved, the effect of substitutes is included in the constant term, or

$$a_{ij^*} = a_j + \sum_{k=3}^{5} b_{kj}S_{kij}$$

and the per capita demand function for lamb is then

$$Q_{ij} = a_{ij^*} + b_{1j}P_{ij} + b_{2j}I_{ij}.$$

Quarterly per capita demand functions for lamb for the four household regions are derived utilizing the above procedure. The derivation of the linear equation for the Northeast household region for the first quarter is as follows:

The first quarter demand equation from Table 1 is

$$Q = -4.5407 - 2.0839P + .9318S_3 + .0428S_4 + .1358S_5 + 1.083I,$$

with the income coefficient for the Northeast (from Table 2) substituted for the U.S. income coefficient. Linear price and income coefficients are calculated from the direct and cross elasticities; for example,[13]

$$b_1 = -2.0839\,\frac{1.1}{.7357} = -3.1156.$$

[13] Average values of the variables for the first quarter in 1967 were: $P=\$.7357$, $S_3=\$.6137$, $S_4=\$.6670$, $S_5=\$.3810$, $Q=1.1$ pounds, and $I=\$2630$.

Table 3. Quarterly per capita demand functions for lamb, by household region, 1967

Quarter	Household[a] region	Calculated coefficients: Intercept	Price of lamb	Income

4	NE	2.1373	−2.2593	.00033
	NC	1.6108	−2.2593	.00017
	S	1.6015	−2.2593	.00019
	W	3.0411	−2.2593	−.000027

[a] The 20 regions utilized in the analysis, as listed in footnote 5, are located in the following household regions: Northeast, region 20; North Central, regions 9, 10, 11, 14, 15, 16, and 17; South, regions 12, 13, 18, and 19; and West, regions 1, 2, 3, 4, 5, 6, 7, and 8.

Similar calculations for the coefficients for substitute meats and income yields the linear equation,

$$Q = a - 3.1156P + 1.6702S_3 + .0706S_4 + .3921S_5 + .00041I.$$

To solve for the constant, we set the above equation equal to estimated first quarter Northeast household region consumption of 2.7812 pounds. Including the effect of substitutes in the constant term, the per capita demand function for the Northeast for the first quarter is

$$Q = 2.7735 - 3.1156P + .00041I.$$

Quarterly per capita demand functions for lamb derived by the above procedure are presented for the four household regions in Table 3.

Regional retail level demand relationships were then derived from the functions in Table 3 by the following procedure:

(1) Select the household demand function for the region being considered.

(2) Multiply regional per capita disposable income by the income coefficient and include in the intercept value.

(3) Multiply the per capita demand function by population to obtain regional demand.

This procedure can be illustrated for region 20 for the first quarter. Since region 20 is located in the Northeast household region, the appropriate equation (from Table 3) is

$$Q = 2.7735 - 3.1156P + .00041I.$$

Estimated per capita income for region 20 in 1967 was $3,100 and estimated population was 52,681,000. Adding the income effect to the intercept term and multiplying by population yields the regional demand function,

$$Q = 213{,}068{,}304 - 164{,}132{,}923P.$$

A summation of total demand over 20 regions for a quarter is used in the iterative solution of the transhipment model.[14]

Supply

There is marked regional variation in the percentage distribution of fat and fed lamb sales by quarter. Table 4 shows that the largest

[14] The solution procedure is described by King and Schrader [6, p. 362]. Regional demand functions by quarter, regional population, and regional per capita disposable income are presented in [9].

[a] Estimates of the number of lambs marketed by quarter are based on information received from state experiment station sheep specialists and sheep industry representatives. For more detail see [9].

number of lambs are sold in the first and third quarters. Most lambs sold in the first quarter are fed lambs, while fat lambs dominate sales in the third quarter. Because of seasonal variations in lamb prices, the marketing pattern of a particular region influences total revenue from lamb. Both regional supplies of lamb and regional feeding capacities were assumed perfectly inelastic at levels existing in 1967.

Imports

New Zealand and Australia are the major sources of fresh and frozen lamb imported into the United States. The quarterly distribution of lamb imports for 1958 to 1967 is shown in Table 5. The percentage distribution of imports by quarter shows considerable variation, but for seven of the ten years the largest quantity of imports entered during the first and second quarters. Imports averaged about 12.75 million pounds annually between 1964 and 1967.

During 1967, an estimated 68 percent of lamb imports entered the United States through ports in the Northeast (region 20), and most of the remainder entered West Coast ports (retions 1 and 2). The estimated quarterly and annual distribution of 1967 lamb imports by port of entry is presented in Table 6.

The Results

Producer costs

Lamb imports can be expected to reduce average prices received by domestic lamb producers (ceteris paribus). The reduction is not, however, uniform among regions, since the quarterly marketing pattern, retail price for

carcass lamb, average slaughter weight, dressing percentage, and marketing margin determine a region's total revenue from lamb and each of these factors varies by quarter and/or region. The extent of regional variation in the impact of imports is illustrated by data in Table 7. Regional average and total farm returns for lamb, assuming an equilibrium solution under conditions as specified, are presented for Model I (no imports). Percentage decreases in total revenue due to the level of imports in Model II and Model III are also shown in Table 5. The 1967 level of imports (Model II) resulted in a \$3.67 million (1.61 percent) decrease in total revenue. Regional decreases in total revenue ranged from 1.36 percent in region 6 to 1.85 percent in region 13. An increased level of imports (Model III) resulted in a \$7.8 million (3.43 percent) decrease from Model I equilibrium returns. Regional decreases in total revenue ranged from 2.81 percent in region 6 to 4.75 percent in region 2.

The majority of regional differences in the impact of imports on farm returns are due to two factors—the quarterly level of imports and the quarterly sales pattern of the region. The quarterly level of imports and the price elasticity of demand determine the decrease in quarterly prices. Under Model II the price impact of imports averaged 35 cents per lamb in quarter 1, 46 cents per lamb in quarter 2, 34 cents per lamb in quarter 3, and 21 cents per lamb in quarter 4. The price impact under Model III averaged 68 cents per lamb in quarter 1, 97 cents per lamb in quarter 2, 69 cents per lamb in quarter 3, and 43 cents per lamb in quarter 4. It is obvious that any region marketing a high proportion of its lamb crop in the second quarter will suffer an above-average decrease in total returns; regions marketing the

19	21.66	6.20	1.70	3.51
20	21.86	2.99	1.64	3.36
Total	20.93	227.45	1.61	3.43

[a] Model I has no imports; Model II includes 13.146 million pounds of imports (1967 level); Model III has 26.292 million pounds of imports. The value of lamb imports is not included in calculating total revenue at the farm level.

[b] Values are an average of quarterly prices weighted by quantities shown in Table 4. Quarterly farm prices were calculated by multiplying retail prices by average carcass weight to obtain the value of a lamb carcass. Average carcass weights for the four quarters were 52.15, 49.39, 47.78, and 50.48 pounds. The retail value of a carcass was then multiplied by the farmer's share of the retail value to obtain farm value. The farmer's share of the retail value for the four quarters was 51, 57, 54, and 52 percent.

largest proportion of their lamb crop in the fourth quarter will incur below-average decreases in total revenue. Regions 2, 5, 11, 13, and 18 marketed over 40 percent of their lamb crop in the second quarter; and regions 6, 7, and 8 were the only regions with over 35 percent of annual sales in the fourth quarter (Table 4). The regional impact of imports, as illustrated in Table 7, could easily be changed with a different quarterly pattern of imports, i.e., imports peaking in the fourth rather than in the second quarter.

Larger than average price decreases occurred in regions 1 and 2 during the second quarter under Model III when increased imports were forced to enter these regions. Compared with an average price decrease of 97 cents, region 1 had a price decrease of $1.68 per lamb and the decrease in region 2 was $1.60 per lamb. As previously discussed, increased imports in these regions changed them from importing to exporting regions. The solutions for Models I and II in the second quarter showed region 3 shipping to region 1 and region 5 shipping to region 2. The increase in imports under Model III yielded a solution in which region 1 shipped to region 4 and region 2 shipped to regions 4 and 20. Since region 20 (the Northeast) also receives imports, one would not expect this situation to persist over time. However, this does indicate a type of short-run price impact that can result from imports.

Most of the remaining regional differential in the impact of imports can be explained by changes in optimum shipment patterns. The price impact of imports in regions 12, 13, and 18 was 26 cents per lamb; and it was 28 cents per lamb in region 19 under Model II, compared with the average of 35 cents per lamb. The solution for Model I in the first quarter had region 12 shipping to regions 13, 18, 19, and 20. With the Model II level of imports, region 12 stopped shipping to regions 19 and 20; region 11 shipped to region 18; and region 14 shipped to region 19. Prices for the Model III solution for the first quarter averaged 68 cents per lamb below Model I results. Smaller than average price decreases of 56 cents per lamb in regions 12 and 13; 59 cents per lamb in region 18; and 61 cents per lamb in region 19 were the result of changes in shipment patterns. Model I results for the first quarter are presented above. With the Model III level of imports, region 12 stopped shipping to regions 18, 19, and 20; region 11 shipped to regions 11 and 18; and region 14 shipped to region 19.

During the fourth quarter under Model III we find a price decrease of 35 cents per lamb rather than 45 cents in regions 12, 13, and 18. Under Model I and Model II, region 12 shipped to regions 13, 18, and 20. Under Model III, region 12 no longer shipped to region 20 and region 11 shipped to region 18.

The percentage impact of lamb imports on net returns is of course much higher than on total returns. A measure of the impact of Model II and Model III levels of lamb imports on estimated net returns is shown in Table 8. A dollar return to the land resource for each fat and feeder lamb produced is presented for each region for the three model situations.[15] As shown,

Table 8. Estimated regional returns to the land resource per lamb, three levels of imports, 1967 conditions

15	1.93	1.57	1.19
16	4.22	3.89	3.54
17	5.33	4.98	4.61
18	10.36	10.00	9.61
19	.25	(.09)	(.46)
20	(.91)[b]	(1.26)	(1.63)

[a] These figures include estimated federal shorn and unshorn wool payments, wool sales, and returns for culls. Thus, it is a net return per lamb for the total sheep enterprise. Factors such as lambing percentage, selling weight, proportion selling as fat lambs and feeders, regional feed costs, and other costs of production, including a return for management, were included in the calculations. The tabled figures can be converted to a percentage return on land investment by dividing by the investment in land required to produce one lamb.
[b] Parentheses denote a loss.
Source: [9].

there is considerable variation in net returns to land for each of the three models. For Model I, returns range from a high of $13.71 per lamb in region 5 to a loss of 91 cents per lamb in region 20. With imports, we find two regions with negative returns under Model II and four regions under Model III.

Consumer benefits

Lamb imports provide an increased supply of lamb at lower prices for consumers. Our analysis provides an estimate of these consumer benefits.

The Model II level of lamb imports increased the amount of carcass lamb available to consumers by 4.4 percent. Equilibrium quantities increased from 2.3 to 3.6 percent in regions located in the West household region (regions 1, 2, 3, 4, 5, 6, 7, and 8); from 9.5 to 14.5 percent in regions located in the North Central household region (regions 9, 10, 11, 14, 15, 16, and 17); from 10.4 to 17.9 percent in regions located in the South household region (regions 12, 13, 18, and 19); and 2.2 percent in the Northeast household region (region 20). Equilibrium retail prices for carcass lamb decreased an average 1.63 percent. There was little regional variation in price decreases, with the range being 1.52 to 1.70 percent (1.22 to 1.32 cents per pound).

The Model III level of imports increased the amount of carcass lamb available to consumers by 8.1 percent. Equilibrium quantities increased from 4.9 to 6.3 percent in regions located in the West household region; from 14.3 to 29.7 percent in regions located in the North Central household region; from 21.3 to 36.6 percent in regions located in the South household region; and 4.4 percent in the Northeast household region. Price decreases ranged from 3.2 to 4.1 percent (2.47 to 3.28 cents per pound) with an average decrease of 3.47 percent.

Some Implications

The analysis illustrates a few of the many factors that must be considered in attempting to estimate the price impact of lamb imports. The level and timing of imports, and combined with seasonal and regional characteristics of domestic supply and demand, produce pronounced regional variation in the annual price impact of imports. Quarterly marketing patterns, restricted ports of entry for imports, and changes in optimum distribution patterns account for most of the regional variation. Quarterly import quotas could be used to equalize the regional impact of imports associated with quarterly marketing patterns. For instance, with 1967 imports of 13.1 million pounds, we estimated that a distribution of 4.32 million pounds in quarter 1, 3.43 million pounds in quarter 2, 2.23 million pounds in quarter 3, and 3.14 million pounds in quarter 4 would have equalized the average quarterly impact of imports.[16] However, the increase in total industry revenue from this equalization is so small under 1967 conditions that the procedure hardly seems worthwhile.

The effect of promotional activities by domestic producers and exporters was excluded

[15] The tabled figures are a combination of land and location rents. It is impossible to separate quality and location factors, since over time locational advantages get imputed into the price of land.

[16] To allocate quarterly imports properly, the demand relationships should be reestimated with price the dependent variable. For a discussion of the allocation procedure and statistical considerations, see Waugh [17, pp. 87–91].

from the analysis. Thus, the decreases in total revenue to producers and price benefits to consumers must be considered as maximums. Even so, they were not large for the 1967 level of imports. Producers' revenue was decreased by 1.61 percent; retail prices for carcass lamb declined an average of 1.63 percent. It is clear, however, that sharply increased levels of lamb imports must be accompanied by promotional activities if domestic producers' returns are to be maintained.

Import restrictions on fresh and frozen lamb meat have been and will continue to be proposed. These restrictions could take the form of annual and/or quarterly quotas, tariffs, market sharing arrangements, and joint promotional activities by importers and domestic producers. This paper emphasizes that a number of factors must be considered in light of the stated goals of a particular proposal. Unrestricted or restricted lamb imports have regional as well as industry-wide implications.

Research Notes

Comparative Investment per Worker in Agriculture and Manufacturing Sectors of the Economy

Allen G. Smith

Investment in production assets per farm worker in agriculture has increased 15 times since 1940 and more than doubled in the last 10 years. Substitution of capital for labor through increased mechanization of farming operations has resulted in a reduction in farm workers and increased investment in production assets. The introduction of the mechanical cotton harvester is an outstanding instance of the substitution of capital for labor, along with grain combines, corn pickers, potato harvesters, and fruit pickers.

How does investment per worker in agriculture compare with investment per worker in the manufacturing industry? Generally, the comparison is made between asset data from the *Balance Sheet of the Farming Sector* for agriculture and data from the *Quarterly Report of Manufacturing Firms* for manufacturing. Assets are not valued the same way, however, for these two reports. Agricultural assets are valued on a current basis—that is, essentially, an inventory of physical units is multiplied by the current market value per unit. Assets for manufacturing enterprises, on the other hand, are compiled from financial statements of manufacturing firms and are generally values based on cost less capital consumption (depreciation plus other capital disappearance allowances). In inflationary periods, especially, the two values are not comparable.

A second problem in comparing agriculture with manufacturing is the definition of a production worker. Most farms combine labor and management in one individual, with one or two additional hired workers. In manufacturing, management and labor are generally separated. For example, the average employment in manufacturing during 1968 was 19.7 million persons, but production workers numbered only 14.5 million.

Using average number of total farm workers, including both self-employed and hired, and average number of production workers only for manufacturing, average investment per farm worker was $50,020; per production worker in manufacturing enterprises, $35,222. Using this approach, the investment per worker on farms is almost one and one-half times as much as in manufacturing enterprises. The investment per employee, including both production and management, in manufacturing enterprises is $25,846; on this basis, agriculture's investment is almost twice that of manufacturing.

In the 1969 *Balance Sheet of the Farming Sector* assets in farming on a cost basis were estimated to be $136.9 billion, or $28,833 per farm worker. The cost basis is more comparable to the book value of manufacturing firms than current values. Depreciable assets are usually carried on manufacturing firm balance sheets at cost less depreciation. Nondepreciable items, such as land (the largest value item in agriculture but relatively minor in manufacturing), are shown at cost.

The value of land has appreciated rapidly in recent years. This land appreciation, combined with a declining number of farm workers, has tended to increase the value of production assets per worker very rapidly when calculated on a current value basis. The cost basis, therefore, appears to be more comparable to book value than current value basis.

All workers in both agriculture and manufacturing should be included in estimating investment per worker. With all workers in-

Allen G. Smith *is agricultural economist with the Economic Research Service, USDA.*

cluded and with farming assets valued on a cost basis, investment per farm worker in 1969 was \$28,833 as against \$25,846 per worker in manufacturing enterprises. Investment per worker, on this basis, still appears to be higher in agriculture than in manufacturing, but only by about 10 percent, not 50 to 100 percent.

Consequently, data that are often interpreted as indicating a relatively large and rapidly rising capital/labor ratio in farming are reflecting mainly the combined effect of rising land values and a declining number of farm workers.

Nonfarm Income Earned by Commercial Farm Operators in Central Illinois*

R. J. Hanson

A study for the United States was reported by Reinsel on the amount of income received from various sources by individuals who derive some of their income from farming [2, p. 2]. That study indicated several national trends in nonfarm income and provided further detail to estimates published by ERS annually in *Farm Income Situation*. Yet there is a need for further information concerning the nonfarm income earned by farmers, especially commercial farm operators.

The purpose of this study was to determine the amounts and sources of nonfarm income earned by commercial farm operators in central Illinois. Total nonfarm income and amount by source were compared at different levels of farm and family earnings, age, and education; the various off-farm occupations of farm operators and farm wives were determined; and differences in the characteristics of farm operations were analyzed for farm operators who received wage and salary incomes and those who did not.

Off-farm employment can supplement farm income, perhaps covering occasional farm income losses, and can also stabilize total family income. Nonfarm jobs might change the structure of farming, as for example by replacing part or all of the livestock in some farm operations.

The Sample and the Data

Information for this study came primarily from 1968 cooperators in the Illinois Farm Business Farm Management Association, whose records provided farm and nonfarm income amounts for each operator. Questionnaires completed by farm management fieldmen in the study area furnished supplementary data, including the off-farm occupation of farm operator or his wife or both, place of employment, educational level, and age of farm operator.

The sample involved 299 commercial farm operators for a seven-county area in the southwest portion of central Illinois,[1] which represented 2.27 million acres and a 1968 population of 277 thousand. Springfield (population 89,816) is the only metropolitan city within the study area. Peoria (population 125,736) is 22 miles north of the study area.[2]

The sample area, generally considered a cash grain and livestock producing area, included farm operators on Class I, II, and III farms. Landlords were excluded, as were operators who were both farmers and landlords.

Empirical Findings

Nonfarm income comprised about 20 percent of the total realized income earned by all farm operators. Sources of this income are given in Table 1. All but one farm operator in the study reported some source of nonfarm income. One of every six operators reported a nonfarm income greater than his realized net farm income. The majority of farm operators reported several different sources of nonfarm income.

The farm operators in this study had an average total realized income of $11,187, of which $2,306 (about 20 percent) was nonfarm income.

Wage and salary income

Off-farm employment of farm wives was the leading source of both wage and salary income

and total nonfarm income. One of every four wives had nonfarm employment, and these accounted for 72 percent of the total wage and salary income and 44 percent of the total nonfarm income.

The average wage and salary income earned by farm wives working off the farm was $4,216. Most working farm wives held full-time jobs that required special skills or advanced education such as teaching, nursing, and secretarial work (Table 2). Families in which the farm wife was working outside the home had fewer children (1.96) than families in which the wife was not working (2.25).

Farm operators working off the farm earned 28 percent of the total wage and salary income and only 17 percent of the total nonfarm income. Most of them held part-time jobs off the farm, as suggested in Table 2, and their average wage and salary income was $1,405.

Farm operators who reported $2,000 or more from wages and salaries, whether earned by himself or his wife, accounted for 90 percent of the total wage and salary income and comprised 21 percent of all farm operators. This group had an average wage and salary income of $5,942. Farms for this group tended to have smaller acreages and fewer livestock than farms in which no wage and salary income was reported.

Relation of nonfarm income to operator characteristics

Farm and family earnings.—Total nonfarm income and wage and salary income decreased as farm and family earnings increased. Farm and family earnings are defined as the value of farm production less cash operating expenses and depreciation [1, p. 13]. Farm operators with negative farm and family earnings (−$389) nevertheless received a total realized income of $3,837, because of their off-farm earnings. Average nonfarm income was $4,226 for these operators; only $815 for operators with farm and family earnings of $20,000 or more.

Nonfarm income was a smaller percentage of the total realized income for operators with higher farm and family earnings. On the other hand, income received from interest plus dividends was a larger proportion of the total nonfarm income as farm and family earnings increased, and wage and salary income was a smaller percentage.

Age of operator.—Total nonfarm income, wage and salary income, and the proportion of the total realized income accounted for by nonfarm income increased with age of farm operator up to 61 years or older (Table 3). Farm operators under 41 years of age reported the lowest levels of nonfarm income; those between 51 and 60 received the largest amounts of wage and salary income, nonfarm business income, and interest.

Education of operator.—Total nonfarm income and wage and salary income increased with higher education levels of farm operators. In contrast, there were no significant increases in farm income for different levels of education, as suggested in Table 4. Nonfarm income comprised 10 percent of the total realized income for farm operators with grade school education;

Table 3. Farm and nonfarm income averages of farm operators by age classifications

	Age (years)				
	20–30	31–40	41–50	51–60	61 and over
			dollars		
Total realized income	8,990	8,690	11,846	14,714	8,869
Total realized net farm income	7,944	7,615	9,434	10,342	6,967

Pensions	0	0	0	16	38

52 percent for operators with college degrees.

Farm operators with college educations received an average nonfarm income ($7,071) that was greater than their average realized net farm income ($6,498). Besides earning the highest wage and salary income, operators with college degrees also acquired the highest nonfarm business income, interest, and dividends.

Farm wives whose husbands had college degees had an average off-farm income of $1,082, which accounted for 15 percent of the total nonfarm income reported by their husbands (see Table 4). In contrast, wives whose husbands had some college training earned 63 percent ($1,765) of the total family nonfarm income, while wives of husbands with just high school education contributed 55 percent ($1,097) to their total family nonfarm income. These data, on the surface, do not appear to support the general notion that going through college is correlated with acquiring a well-educated and therefore highly employable wife. For those farm operators with grade school education, none of the wives received off-farm income. This combination of findings, for operators with college degrees compared with those with only high school or grade school education, is compatible. Whether a farmer's wife is employed for wages or salary depends on both ability and desire to adopt this course of action. The wife of a farm operator who has a college degree may have the ability to obtain remunerative employment but for a variety of reasons may choose not to do so.

Table 4. Farm and nonfarm income averages of farm operators by levels of education

Trusts	0	44	73	0	266
Pensions	83	0	1	0	26

Conclusions

Although this study consisted entirely of commercial farm operators, some of these operators have successfully combined off-farm employment with their farm operation. It may be that improving capabilities for handling larger volumes allow farm operators to combine part-time nonfarm employment with their commercial farm operations. Furthermore, in this era of a rapidly changing structure in farming, off-farm employment could be a variable affecting the direction and rapidity of this change, such as replacing part or all of the livestock in some farm operations.

The ability of commercial farm operators, as well as other farmers, to continue farming while also holding off-farm employment has important implications for the farm-business organization, public-policy considerations, and resource allocations within agriculture. Nonfarm income may be quite important, even for commercial farm operators, in closing the income gap between farm and nonfarm workers.

Feed Formulation For Least Cost of Gain

J. A. McDonough

The conventional least-cost ration criterion for feed blending will not necessarily result in the cheapest ration overall. Lofgreen [1] has shown that an animal's "maintenance energy" requirement must be met before food energy can be converted to production. He has evaluated the effectiveness of the food energy content of various feedstuffs for use in maintenance (NE_m content) as well as their effectiveness towards production (NE_p). It is the interaction of these two "effectiveness factors" that usually prevents a minimum-cost ration from being the optimal overall solution unless provisions are made to take these factors into account. This paper derives an *LP* method for solving for the least cost of gain ration.

A property of any given feed mixture that meets other nutritional requirements on protein content, fiber, vitamins, etc., is the cost per pound of gain that would be achieved if the ration were fed. This very important property of the ration may be estimated by using Lofgreen's concepts. Consider an average animal of a given weight and type (a 600-pound steer, for example). Lofgreen's tables or their generating equations [2] may then be consulted and the maintenance requirements extracted from them (5.21 Mcal. per day). The other data required would be the additional "production energy" intake equivalent to a pound of gain at the expected performance level. For example, if gain will be in the neighborhood of 3.0 pounds, the energy equivalent of a pound of gain is 5.64/3 or 1.88 Mcal. per pound. Finally, we must establish how much feed the animal will consume daily. For simplicity, 0.25 percent (on a dry basis) of the animal's weight is used here, but any equation predicting feed consumption (such as those in the cattle simulator developed by Dr. Meredith Smith of IBM) could be used. This is an important consideration as an examination of the gain cost equation (5) shows that the amount that an animal will eat is a very large factor in determining the optimum ration.

Now consider any general feeding specification, as supplied by a nutritionist, that will formulate a palatable ration with a balanced nutritional content (i.e., specifications of the desired percentage limits or ranges on protein, fiber, supplement, etc.). Note that we are not discussing a set of rations that vary slightly in (say) NE_p content. The development here will formulate the absolute minimum gain cost ration, not merely select the one with the least gain cost from a set of rations.

For maintenance, the animal will use the following pounds per day of feed, assuming an environment where thermo-neutrality is possible:

$$(1)\quad 5.21/NE_m = \text{pounds of feed used for maintenance.}$$

The balance of the ration consumed will provide energy that is usable for production. (Consumption basis is 15 pounds dry or $15/D$ on an as-is basis.)

$$(2)\qquad (15/D - 5.21/NE_m)NE_p = E_g$$

The daily gain may then be computed using the Lofgreen production energy equivalence constant.

$$(3)\qquad E_g/1.88 = g$$

The total cost per day of the ration is

$$(4)\quad (15/D)C = \text{total cost of feed per day}$$

Division yields the daily cost per pound of gain, G_c:

$$(5)\quad G_c = \frac{C\cdot 15/D}{(15/D - 5.21/NE_m)\cdot NE_p/1.88}$$

Defining the constants $A_1 = 1.88$ and $A_2 = 5.21/15.0$, the gain cost, G_c, of a ration may then be written as

$$(5)\qquad G_c = \frac{A_1 C/NE_p}{1 - A_2 D/NE_m}$$

or in expanded form

$$(5)\qquad G_c = \frac{A_1(\sum C_i X_i)/(\sum E_i X_i)}{1 - A_2(\sum D_i X_i)/(\sum M_i X_i)}$$

Now consider the definition of the derivative of G_c:

J. A. McDonough *is an advisory systems engineer with the International Business Machines Corporation.*

$$(6)\qquad \begin{aligned} dG_c &= \frac{\partial G_2}{\partial X_1}\,dX_i + \frac{\partial G_c}{\partial X_2}\,dX_2 + \cdots \\ &= \sum \frac{\partial G_c}{\partial X_i}\,dX_i \end{aligned}$$

These $\partial G_c/\partial X_i$ are calculable but are exact only for the set of X_i from which they are derived. However, they are good approximations if the composition of the mixture is not changed radically and may be used to compute the change in the cost of gain resulting from a change in the values of the X_i in the following manner.

Applying finite difference notation, equation (6) may be written as a difference equation:

$$(7)\qquad \Delta G_c = \sum \frac{\partial G_c}{\partial X_i}\,\Delta X_i = \sum Z_i \Delta X_i$$

and since a difference for any variable, V, may be defined as $\Delta V = V_{new} - V_{old}$, we may write

$$(8)\qquad \begin{aligned} &(G_c)_{new} - (G_c)_{old} \\ &\qquad = \sum Z_i(X_i)_{new} - \sum Z_i(X_i)_{old} \end{aligned}$$

Since $(G_c)_{old}$ and $Z_i(X_i)_{old}$ are constant, the minimization of $\sum Z_i(X_i)_{new}$ would minimize G_c. Thus, if the Z_i are substituted for the cost coefficients in a linear programming formulation, we may solve for a new set of X_i (the ration composition vector); and this new ration will be a closer approximation of the least gain cost ration. The rigor of the technique is defensible only if the changes in composition are small, but repeated iterations have never failed to converge to a unique solution.

If the daily gain, g, is relatively constant (i.e., energy content of the ration has been constrained by the nutritionist), we may use the following analytic equation to evaluate the Z_i:

$$(9)\qquad \begin{aligned} Z_i &= \frac{G_c C_i}{C} - \frac{G_c E_i}{NE_p} + \frac{A_2 G_c}{1 - A_2 D/NE_m} \\ &\quad \cdot \left(\frac{D_i}{NE_m} - \frac{DM_i}{NE_m{}^2}\right). \end{aligned}$$

However, a good general method suitable for computer use is to compute Z_i by finite difference methods:

A step-by-step method for formulating the least cost of gain ration follows:

1. Determine size of animal (average), expected consumption, NE_m requirement, and evaluate coefficient A_2.
2. Utilizing the LP model that contains all nutritional and palatability limitations on protein, fiber, minerals, vitamins, supplement, etc., that is supplied by the nutritionist, solve for the least cost of feed ration.
3. Utilizing the resultant set of X_i, solve for the NE_m and NE_p content of the new ration. Then obtain the daily gain and reevaluate A_1. Finally, solve for the gain cost, G_c, (equations (2), (3), (4), (5)).
4. Using the set of X_i obtained from the LP, solve for the Z_i for *all* major ingredients available (equation (9) or (10)). Note that all ingredients must be treated, as it is not unlikely for an ingredient to be pulled back into the least gain cost solution where it was driven to zero level in the least feed cost solution.
5. Using the set of Z_i as costs, re-solve the LP and get a new set of ingredient levels, X_i.
6. Repeat step 3 and 4 using the latest set of X_i. When the Z_i do not change appreciably, the solution has been obtained.

It is usually not necessary to repeat the LP more than once, especially if a reasonably close first guess of the optimum composition vector is made. In fact, if only a few ingredients are available, the least cost of feed solution is likely to be the least gain cost solution also. In general, this method requires much less computer time than other methods that involve multiple LP solutions.

The mathematical development has assumed A_1 to be nearly constant. This is usually the case where the nutritionist has specified the energy content of the ration within narrow limits as this effectively fixes the rate of gain. However, in the general case, we may utilize Lofgreen's generating equation:

$$(11)\qquad A_1 = B_1 + B_2 g$$

Then, using equation (3), we may write an equation for A_1 in terms of E_g.

$$(12)\qquad A_1 = 0.5(B_1 + \sqrt{B_1{}^2 + 4B_2E_g})$$

Substituting this into the gain cost equation

$$(10)\qquad Z_i = \frac{G_c(X_1, X_2, \cdots, X_i + 0.01, \cdots) - G_c(X_1, X_2, \cdots, X_i \cdots)}{0.01}.$$

yields

$$(13) \quad G_o = \frac{0.5C(B_1 + \sqrt{B_1^2 + 4B_2E_g})}{(1 - A_2D/NE_m)NE_p}$$

This equation may be used to develop the Z_i for a completely general solution.

The technique is by no means limited to this use in feeding cattle and could be extended to (say) maximizing dairy production or swine production. The only requirement is that the optimum sought be capable of being expressed as a function of the ingredient level, as is the cost of gain, G_o.

Definitions of Terms

- X_i Proportion of feedstuff I in a ration expressed as a fraction.
- NE_p Net energy usable for production for a given ration or blend (Mcal. per pound).*
- NE_m Net energy for maintenance available from a given ration (Mcal. per pound).*
- G_o Gain cost (dollars per pound of production).
- E_i NE_p of feedstuff$_i$, (Mcal. per pound).*
- M_i NE_m of feedstuff$_i$, (Mcal. per pound).*
- D Dry matter fraction of a ration.
- D_i Fraction of dry matter in feedstuff$_i$.
- C Unit cost of a finished ration (dollars per pound).
- C_i Unit cost of feedstuff$_i$ (dollars per pound).
- Z_i $\partial G_o/\partial X_i$ = partial derivative of the gain cost with respect to a change in feedstuff$_i$.
- A_1 The average energy required for production, Mcal. per pound gained.
- A_2 A constant used to simplify the equations; equal to the daily maintenance energy requirement of an animal divided by 15.
- W Animal weight (pounds).
- g Daily gain in weight (pounds).
- E_g Energy available for gain (Mcal).
- B_1 Constant (600-pound steers only) $= 0.013225\ W^{.75} = 1.604$.
- B_2 Constant (600-pound steers only) $= 0.000778\ W^{.75} = 0.094$.

* Tabulated values are commonly given in Mcal. per 100 pounds on a 90 percent dry basis, but these equations are derived on an as-is basis.

A Note on the Definition of the Economic Region of the Production Function*

RICHARD S. JOHNSTON AND A. GENE NELSON

SEAGRAVES AND PASOUR (hereafter S-P) offer a strong argument for accepting a cost-oriented definition of the "uneconomic regions" of the production function in the theory of the firm [3]. We hope in this note to make a few amendments to the S-P argument and, in so doing, to cast further doubt on the usefulness of the traditional "stages of production" notion as a pedagogical device.

To illustrate the problems with conventional definitions of "economic region," S-P have employed a homogeneous production function. They also, implicitly at least, assumed the "fixed factor" to be perfectly divisible.[1] We shall argue that:

1. In the case of a two-input production function, when one input is *fixed* and ***indivisible***, the firm facing constant input and product prices will choose not to produce if output price falls below average variable costs. The reason for this is *not* that the marginal physical productivity of the "fixed input" is zero at the output corresponding to minimum average variable costs (this is true, however, for linear and homogeneous production functions), but rather that if the firm produces when product price is less than average variable costs, it will earn a negative quasi-rent. For some functions, the marginal physical productivity of the "fixed factor" may be negative at the minimum average variable cost output. The firm may wish to employ fewer units of that factor but is unable to do so because of its indivisible nature. Thus, production where the marginal physical productivity of an input is negative need not imply "uneconomic" production.

2. In the case of a two-input production function, when one input is *fixed* but ***divisible***, the firm facing constant input and product prices will combine inputs so that the marginal physical productivities of both inputs are nonnegative.

Thus, we shall recommend that discussion of production stages as traditionally presented should be either dropped from textbooks on microeconomic theory or amended to include explicit specifications on

(a) the nature of the production function;
(b) the nature of the factor fixity;
(c) product and factor price relationships.

To begin, we shall retain the production function employed by S-P and, with them, assume constant product and factor prices. Thus we satisfy our own criteria (a) and (c).[2] Their production function is

$$y = \frac{x_1^2x_2 - 0.1x_1^3}{x_2^{\alpha}} \tag{1}$$

which is homogeneous of degree $(3-\alpha)$ in x_1 and x_2. S-P considered three cases: $\alpha=2$, $\alpha=1.5$, and $\alpha=2.5$, in order to examine the technical relationships between x_1 and x_2 when the production function is homogeneous of degree one, greater than one, and less than one, respectively. Setting $x_2=1$ yields the short-run product curve

$$y = x_1^2 - 0.1x_1^3 \tag{2}$$

which holds irrespective of the value of α [3, p. 196].

Following an argument advanced by Mundlak [2], S-P show that, for homogeneous production functions in x_1 and x_2, when the marginal physical productivity of x_2 ($MPPx_2$) is negative, the ratio of the marginal physical productivity of x_1 ($MPPx_1$) to the average physical productivity of x_1 ($APPx_1$) must be greater than the degree of homogeneity of the function. Thus, only for linear and homogeneous production functions does the value of x_1 for which $APPx_1$ is maximum correspond to the value of x_1 for which $MPPx_2=0$, since at the maximum value of $APPx_1$, $APPx_1=MPPx_1$. If the degree of homogeneity is less than one (as when $\alpha=1.5$),

* The authors acknowledge the helpful comments of John A. Edwards, James Seagraves, and members of a graduate seminar in production economics at Oregon State University. Published as Oregon Agricultural Experiment Station Technical Paper No. 2878.

[1] This note was prepared prior to the publication of John M. Gates' comment in this Journal [1], in which he does distinguish divisible from indivisible "fixed" factors in discussing the economic region of production. This paper analyzes some implications of this important distinction.

RICHARD S. JOHNSTON *is assistant professor of agricultural economics and* A. GENE NELSON *is assistant professor of agricultural economics and extension farm management specialist at Oregon State University.*

[2] Although we have yet to specify what these prices are.

the $MPPx_2$ becomes negative at a smaller value of x_1 than where $APPx_1$ is a maximum.

S-P argue persuasively that "... if it pays to use any x_1 at all, it pays to use it at or beyond the point where $APPx_1$ is maximum (and hence average variable cost increasing in the single variable input case)." S-P conclude from this that "*the economic region of production is defined by a decreasing $APPx_i$ and a positive $MPPx_i$ for each input, x_i, while every other input is assumed to be constant*" [3, p. 198]. We feel this to be an unfortunate extension since, by implication, it states that production in any other region is "uneconomic." We submit that a firm with one or more inputs constant, i.e., fixed and indivisible, will operate as long as its short-run variable costs are covered. Whether the marginal physical productivity of a fixed input is positive becomes irrelevant. This is true no matter what the production function in x_1 and x_2 is. Thus, if the short-run product curve is represented by equation (2), the firm will hire five or more units of x_1.[3]

Notice that the nature of the short-run fixed factor has now been specified, in accordance with criterion (b). The argument of the preceding paragraph rests on the assumption that the meaning of $x_2=1$ is that no matter how many units of x_1 are used in producing y, exactly one unit of x_1 is both *used* and *paid for.* Again, presumably x_2 is an indivisible input.

Consider the case where $\alpha=2.5$, so that the degree of homogeneity (and hence the elasticity of production) is .5. S-P argue that since the $MPPx_2=0$ at $x_1/x_2=6$ and is negative where $(x_1/x_2)<6$, the firm would never produce where $(x_1/x_2)<6$.[4] Since $x_2=1$, this means the firm would never hire fewer than six units of x_1. This appears to contradict our earlier finding that the firm would hire five or more units of x_1. If the firm in fact hired five units of x_1, it would appear to be operating uneconomically, by the S-P definition, since $MPPx_2<0$ at $x_1=5$.

[3] $$\frac{y}{x_1}=\frac{x_1^2-0.1x_1^3}{x_1}=x_1-0.1x_1^2;$$
$$\frac{d\left(\frac{y}{x_1}\right)}{dx_1}=1-.2x_1 \quad \text{which} = 0 \text{ when } x_1=5.$$

[4] $$y=[x_1^2x_2-0.1x_1^3]x_2^{-2.5};$$
$$\frac{\partial y}{\partial x_2}=\frac{x_1^2}{x_2^{2.5}}-2.5\frac{[x_1^2x_2-0.1x_1^3]}{x_2^{3.5}}=0 \text{ at maximum.}$$

Given $x_2=1$, $x_1^2-2.5x_1^2+.25x_1^3=0$ which, on solution, gives $x_1=6$.

The difficulty here lies in the meaning of the assumption that $x_2=1$. If the firm must in fact employ one full unit of x_2 (the classic example here is the roadbed of a railroad), the price of y could well be low enough that the firm would employ only five units of x_1. For example, if $Px_1=\$10$ and $Py=\$4$, the firm will employ five units of x_1, produce 12.5 units of y, and earn zero quasi-rent. Of course the firm would in this case prefer to dispose of part of x_2. However, our interpretation of the assumption $x_2=1$ precludes this possibility. On the other hand, if the firm were to combine six units of x_1 with the single unit of x_2 at these prices, it would lose \$2.40.

Suppose that $x_2=1$ were changed to mean that the firm had to *pay* for the services of one full unit of x_2 but that not the entire unit of x_2 had to be employed in the manufacture of y. Here then is a different specification on the nature of "fixity." Notice that the situation is still "short run" in nature, since (a) the firm can hire no more than one unit of x_2 and (b) exactly one unit of x_2 must be paid for. The problem is a constrained profit-maximization problem of the form:

Maximize

$$(3) \qquad Py\cdot y-P_1x_1-P_2x_2$$

subject to

$$(4) \qquad (a) \quad y=\frac{x_1^2x_2-0.1x_1^3}{x_2^{2.5}}$$

and

$$(5) \qquad (b) \quad x_2\leq 1.$$

Notice that P_2x_2 is a "fixed cost" equal to $P_2\cdot 1$, since one unit of x_2 must be paid for whether used in production or not. What is the smallest quantity of x_1 that the firm would ever hire in this situation?

We submit that this question can be answered correctly only in the knowledge of Py and Px_1, as per specification (c) in our earlier list. Since one unit of x_2 must be paid for, the marginal factor cost of $x_2=0$ for $x_2\leq 1$ and $=\infty$ for $x_2>1$. Thus, from the short-run profit-maximizing conditions,

$$(6) \qquad Px_2=PyMPPx_2$$

and

$$(7) \qquad Px_1=PyMPPx_1,$$

we have

$$MPPx_2 = 0$$

and

(6a) $$Px_1 = PyMPPx_1$$

as the conditions to be satisfied.

From our earlier example, in which $Px_1=10$ and $Py=4$, $MPPx_2=0$ when

(6b) $$\frac{x_1^2}{x_2^{2.5}} = \frac{2.5[x_1^2x_2 - 0.1x_1^3]^5}{x_2^{3.5}}$$

i.e., when

(6c) $$x_1^2 = \frac{2.5x_1^2x_2 - 0.1x_1^3}{x_2},$$

which reduces to

(6d) $$x_1 = 6x_2.$$

This is precisely the condition that S-P defined as the beginning of the "economic region of production"; i.e., $x_1/x_2=6$.

With $Px_1=10$ and $Py=4$, condition (7) is

(7a) $$10 = 4\frac{[2x_2x_1 - 0.3x_1^2]}{x_2^{2.5}}$$

Solving (6d) and (7a) simultaneously yields

$$x_2 = .2304$$
$$x_1 = 1.3824$$
$$y = 6.912$$

Here quasi-rent

$$= 4(6.912) - 10(1.3824)$$
$$= 13.824$$
$$> 0.$$

Thus, the firm has reduced its employment of both x_1 and x_2 in the production of y, although it continues to pay $Px_2 \cdot 1$ for x_2.

[5] See footnote 4.

It is important to note that, unless $Px_2=0$, the point (.2304, 1.3824) is *not* on the expansion path for this firm. It is, in fact, on the ridge line corresponding to $MPPx_2=0$. The value of x_1 corresponding to $x_2=1$ on the expansion path depends on the price of x_2 but, of course, must exceed 6.[6] If the firm is forced to use one unit of x_2 in production, it would remain in production in the short run for values of $x_1 \geq 5$, as previously argued.[7] If the firm, although having to pay for one unit of x_2, can reduce the use of x_2 in the production of y, it will locate on the ridge line,[8] the location depending upon Px_1 and Py. In our earlier example, this point is (.2301, 1.3824). The point is that for this particular production function, and on the assumption of divisible fixed and variable factors, one can assign market prices to y and x_1 so that any amount of x_1 may be hired economically, as long as $MPPx_1>0$. To discuss regions of production solely in terms of production relationships, therefore, is misleading.

In the case of this particular homogeneous function, the ridge line corresponding to $MPPx_2=0$ has the equation $x_1=6x_2$; i.e., it is linear. Thus, one can interpret S-P's Figure 3 [2, p. 200] as appropriate as long as one recognizes that the horizontal axis measures the ratio x_1/x_2, where $x_2 \leq 1$. One should not interpret their figure as saying that if $x_2 \leq 1$ the rational producer will hire at least six units of x_1.

Thus we conclude with a plea for abandoning the traditional definitions of economic and uneconomic regions of production. We submit that what is economic depends on the nature of the production function, the nature of the factor inputs, and the nature of market prices.

[6] For this particular function, the "long-run" total cost curve has a shape such that for any $Py>0$ the firm will always choose to remain in business in the long run.

[7] We recognize that the firm would not hire units of x_1 beyond the point at which $MPPx_1=0$.

[8] This argument actually deals with the case of a "divisible and adaptable" plant, as discussed by Stigler in [4].

On the Measurement of Price Elasticity of Demand

S. H. LOGAN, G. C. RAUSSER, AND R. A. OLIVEIRA

K. T. MURPHY [2] extends the method of measuring arc elasticity of demand presented by Lyon and Simon [1], but his approach has some apparent inconsistencies and employs incorrect procedures.

The initial formulation used to estimate arc elasticity of demand for cigarettes by Lyon and Simon is

$$e_p = \frac{\dfrac{Q_2 - Q_1}{Q_1} - \sum^{N}\left(\dfrac{Q_4 - Q_3}{Q_3}\right)\Big/ N}{\dfrac{P_2 - P_1}{P_1}}$$

where

e_p = price elasticity;
Q_1 = consumption for the year ended before price change in the trial state;
Q_2 = consumption for the year beginning after price change in the trial state;
Q_3 = consumption in the comparison states for the year before the price change in the trial state;
Q_4 = consumption in the comparison states for the year beginning after the price change in the trial state;
P_1 = price for the year before change in the trial state;
P_2 = price for the year after change in the trial state;
N = number of comparison states.

The model was applied to data involving price and quantity changes for cigarettes in a particular state. The term

$$\sum^{N}\left(\frac{Q_4 - Q_3}{Q_3}\right)\Big/ N$$

is subtracted from the numerator in order to eliminate the effect of secular changes in quantity demanded and thus permit factoring out the effect of a price change. The subtracted term represents the average percentage quantity change for other states in which prices remained constant. Thus, the assumption is that secular changes (in percentages) in the trial state are equal to the expected (average) value of secular changes in the comparison states.

Murphy comments, "Subtracting $(Q_3-Q_4)/Q_4$ in the 'control' cities implies the authors had in mind an additive model, but nowhere do they indicate they have considered this question. A model linear in logs might seem more reasonable for cigarette demand; if so, this would suggest dividing by $(Q_4-Q_3)/Q_3$—not subtracting. The latter could produce significantly biased estimates of elasticity." While Murphy's two ratios show different ordering of the subscripts, we shall assume he meant the latter ratio since it is the one used by Lyon and Simon.

Murphy also presents the following example in which the demand for cigarettes is postulated as a Cobb-Douglas function of price and disposable personal income:

$$q = a_0 P^{a_1} E^{a_2}$$

where $a_0 = a_2 = 1$, and $a_1 = -1$. Therefore e_p, the price elasticity, equals -1. The points for measurement of the arc elasticity are

Time	"Test" city			"Control" cities (average)		
	q	p	E	q	P	E
1	1	1	1	1	1	1
2	1.32	.833	1.10	1.10	1	1.10

Following Lyon and Simon's derivation, Murphy estimates the arc elasticity as

$$\frac{.32 - .10}{-.167} = -1.32,$$

which represents a difference of .32 from the true point elasticity of -1. He then states, "The bias would be reduced to 20 percent if we *divide* $(\Delta q/q)_T$ by $(\Delta q/q)_c$."[1] However, using Murphy's figures and his outlined procedure,

S. H. LOGAN *is associate professor of agricultural economics and agricultural economist in the Experiment Station and on the Giannini Foundation;* G. C. RAUSSER *is acting assistant professor of agricultural economics and agricultural economist in the Experiment Station and on the Giannini Foundation; and* R. A. OLIVEIRA *is a graduate student in agricultural economics—all at the University of California, Davis.*

[1] In Murphy's notation $(\Delta q/q)_T = (Q_2 - Q_1)/Q_1$ and

$$(\Delta q/q)_C = \sum^{N} \frac{(Q_4 - Q_3)/Q_3}{N}.$$

in no way can we duplicate an arc elasticity figure that varies from the *point* elasticity by 20 percent. In short,

$$\frac{.32/.10}{-.167} = -19.2.$$

Murphy's suggestion that secular changes should be eliminated by division for a multiplicative function is correct; however, the procedure he outlines is wrong.

Consider first the simple linear relationship:

$$q_t^r = a_{0t}^r + b_t^r P_t^r + \sum_{i=1}^{M} a_{it}^r X_{it}^r$$

where

q = quantity demanded
P = price of the commodity
X = all other predetermined variables, e.g., income, price of substitutes, etc.
t = time period 1 and 2
r = states, 1, 2, $\cdots$, N where state 1 is the trial state.[3]

The basic assumptions of the Lyon and Simon model are:

(1) $b_1^r = b_2^r$ for all r;

(2) $P_1^r = P_2^r$ for $r = 2, 3 \cdots N$ (price changes only in region 1); and

(3)
$$\frac{\Delta(a_{0t}^1 + \sum_{i=1}^{M} a_{it}^1 X_{it}^1)}{a_{01}^1 + b_1^1 P_1^1 + \sum_{i=1}^{M} a_{i1}^1 X_{i1}^1} = \frac{\sum_{r=2}^{N} \dfrac{\Delta(a_{0t}^r + \sum_{i=1}^{M} a_{it}^r X_{it}^r)}{a_{01}^r + b_1^r P_1^r + \sum_{i=1}^{M} a_{i1}^r X_{i1}^r}}{N-1}$$

while 1 = the trial state and r = all others $(2 \cdots N)$.

If we let

$$\sum_{i=1}^{M} a_{it}^r X_{it}^r = A_t^r,$$

we can write the arc elasticity as follows:

[3] This notation is a change from that employed by Lyon and Simon in that N now represents the total number of states, both trial and comparison.

unadjusted

$$e_p^1 = \frac{\dfrac{q_2^1 - q_1^1}{q_1^1}}{\dfrac{P_2^1 - P_1^1}{P_1^1}} = \frac{\dfrac{[a_{02}^1 + b_2^1 P_2^1 + A_2^1] - [a_{01}^1 + b_1^1 P_1^1 + A_1^1]}{q_1^1}}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

Since from assumption (1) $b_1^r = b_2^r$,

unadjusted

$$e_p^1 = \frac{\dfrac{b_2^1(P_2^1 - P_1^1)}{q_1^1} + \dfrac{(a_{02}^1 + A_2^1) - (a_{01}^1 + A_1^1)}{q_1^1}}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

The first term of the numerator indicates the change in quantity demanded resulting from the change in price, the effect we are seeking. The term on the right represents changes in quantity demanded resulting from changes in other predetermined variables. Using assumptions (2) and (3),

$$\frac{(a_{02}^1 + A_2^1) - (a_{01}^1 + A_1^1)}{q_1^1} = \frac{\sum_{r=2}^{N} \left(\dfrac{q_2^r - q_1^r}{q_1^r} \right)}{N-1}.$$

Thus, in order to eliminate the non-own-price factors from the basic equation for arc elasticity, we subtract the term on the right and obtain Lyon and Simon's formula:

$$\text{adjusted} \quad e_p^1 = \frac{\dfrac{q_2^1 - q_1^1}{q_1^1} - \dfrac{\sum_{r=2}^{N} \left(\dfrac{q_2^r - q_1^r}{q_1^r} \right)}{N-1}}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

A similar procedure can be followed for a multiplicative function:

$$q_t^r = a_{0t}^r \prod_{i=1}^{M} (X_{it}^r)^{a_{it}^r} (P_t^r)^{b_t^r}$$

The same basic assumptions hold for this model also, i.e.,

(1) $b_1^r = b_2^r$ for all r;

(2) $P_1^r = P_2^r$ for $r = 2, 3 \cdots N$; and

(3)
$$\frac{\Delta a_{0t}^1 \prod_{i=1}^{M} (X_{it}^1)^{a_{it}^1}(P_1^1)^{b_t^1}}{a_{01}^1 \prod_{i=1}^{M} (X_{i1}^1)^{a_{i1}^1}(P_1^1)^{b_1^1}} = \frac{\sum_{r=2}^{N} \dfrac{\Delta a_{0t}^r \prod_{i=1}^{M} (X_{it}^r)^{a_{it}^r}(P_t^r)^{b_t^r}}{a_{01}^r \prod_{i=1}^{M} (X_{i1}^r)^{a_{i1}^r}(P_1^r)^{b_1^r}}}{N-1}$$

where $1=$trial state and $r=$all others $(2 \cdots N)$.

Letting

$$a_{0t}^r \prod_{i=1}^{M} (X_{it}^r)^{a_{it}^r} = A_{0t}^r,$$

we can write unadjusted

$$e_p^1 = \frac{\dfrac{q_2^1 - q_1^1}{q_1^1}}{\dfrac{P_2^1 - P_1^1}{P_1^1}} = \frac{\dfrac{A_{02}^1(P_2^1)^{b_2^1} - A_{01}^1(P_1^1)^{b_1^1}}{A_{01}^1(P_1^1)^{b_1^1}}}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$
$$= \frac{\dfrac{A_{02}^1(P_2^1)^{b_2^1}}{A_{01}^1(P_1^1)^{b_1^1}} - 1}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

The term $A_{02}^1(P_2^1)^{b_2^1} = q_2^1$ contains effects from changes in both own price and other variables which need to be separated. However, we can write

$$\frac{[A_{01}^1(P_2^1)^{b_2^1}][A_{02}^1(P_1^1)^{b_1^1}]}{A_{01}^1(P_1^1)^{b_1^1}} = A_{02}^1(P_2^1)^{b_2^1}$$

In this case, $A_{01}^1(P_2^1)^{b_2^1}$ shows the effect of a price change, holding other factors constant (which is the effect we want); and $A_{02}^1(P_1^1)^{b_2^1}$ indicates the effect of secular changes, holding own price constant. Substituting in the arc elasticity equation:

unadjusted

$$e_p^1 = \frac{\dfrac{\dfrac{[A_{01}^1(P_2^1)^{b_2^1}][A_{02}^1(P_1^1)^{b_1}]}{A_{01}^1(P_1^1)^{b_1^1}}}{A_{01}^1(P_1^1)^{b_1^1}} - }{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

Consider the numerator, which can be writte

$$\frac{[A_{01}^1(P_2^1)^{b_2^1}][A_{02}^1(P_1^1)^{b_1^1}]}{[A_{01}^1(P_1^1)^{b_1^1}][A_{01}^1(P_1^1)^{b_1^1}]} - 1$$

By assumptions (1), (2), and (3),

$$\frac{A_{02}^1(P_1^1)^{b_1^1}}{A_{01}^1(P_1^1)^{b_1^1}} = \frac{\sum_{r=2}^{N} \dfrac{q_2^r}{q_1^r}}{N-1}$$

Thus, if we divide the *first* term of th numerator by the mean ratio of q_2^r/q_1^r wher $r=2 \cdots N$, we are left with

$$\frac{A_{01}^1(P_2^1)^{b_2^1}}{A_{01}^1(P_1^1)^{b_1^1}} - 1$$

which shows the percentage change in quantit demanded resulting from a change in owr price, or

adjusted

$$e_p^1 = \frac{\dfrac{q_2^1/q_1^1}{\dfrac{\sum_{r=2}^{N} \dfrac{q_2^r}{q_1^r}}{N-1}} - 1}{\dfrac{P_2^1 - P_1^1}{P_1^1}}$$

When applied to Murphy's example,

adjusted $$e_p^1 = \frac{\dfrac{1.32/1}{1.10/1} - 1}{-.167} = -1.20$$

which with respect to the *arc* elasticity represents zero bias.

While division is the right procedure, the terms involved differ from those presented by Murphy. In addition to obtaining an incorrect answer, if we divide the two ratios suggested by Murphy we conceivably could obtain a positive

price elasticity even though the underlying demand function followed the usual downward sloping characteristic. For example, assume that secular changes in other regions (as well as in the base region) have resulted in less quantity being consumed in the second time period. On the other hand, assume that price in the trial region drops enough so that quantity demanded increases by more than enough to offset the secular decrease. Following Murphy's suggested procedure, a positive ratio would be divided by a negative ratio giving a negative number which in turn would be divided by the negative percentage change in price, a procedure that would give a positive price elasticity of demand.

A Modified Adaptive Expectations Model*

VAHID F. NOWSHIRVANI

NERLOVE's reformation of Cagan's adaptive price expectations model has become a standard tool in the estimation of agricultural supply functions.[1] In this paper we propose a modified version of Nerlove's model which in addition to past prices takes into account observed deviations of yield from its normal value. We show that under certain assumptions our model has the desirable property of rationality as defined by Muth.

In the first section Muth's concept of rationality and the conditions under which Nerlove's adaptive expectations model is rational are briefly discussed. This is followed by a more general model of which both Nerlove's and this paper's models are special cases.

Adaptive Expectations and Rational Expectations

According to Muth [3], expectations are rational if they "... are essentially the same as the prediction of the relevant economic theory." Defined in this way, the form of the expectations model depends on the structure of the underlying economic model. Muth has shown that Nerlove's model,

$$P_t^* - P_{t-1}^* = \beta(P_{t-1} - P_{t-1}^*)$$

where P_t^* and P_{t-1}^* are expected prices in period t and $t-1$, P_{t-1} is the actual price in period $t-1$, and β is the coefficient of expectations, is equivalent to the rational expectations model under certain conditions. Let us briefly examine these conditions. It is assumed that producers have to form expectations of prices for a commodity whose market is characterized by the following supply and demand equations:

$$Q_t^s = a + bP_t^* + U_t$$

$$Q_t^d = c + dP_t$$

where

- Q_t^s is the quantity supplied;
- Q_t^d is the quantity demanded;
- P_t^* is the market price expected to prevail during the period t;
- P_t is the market price in period t;
- U_t is a disturbance term which may represent variations due to weather or other factors influencing the supply.

If the average price expectation of producers is rational,

$$P_t^* = E(P_t).$$

It can be shown that adaptive expectations satisfy the above condition if the disturbance term U_t is a specific linear combination of independently distributed random variables ϵ_t with zero mean and common variance.[2]

$$U_t = \epsilon_t + \sum_{i=1}^{\infty} w\epsilon_{t-i}$$

$$E\epsilon_j = 0, \qquad E\epsilon_i\epsilon_j = \begin{cases} \sigma^2 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

and

$$|w| < 1.$$

This condition is equivalent to assuming that the random shock, ϵ_t, has both a permanent and a transitory effect on U_t. A positive fraction, w, of ϵ_t permanently affects U_t, while the remainder, $1-w$, is transitory and thus has no effect on subsequent values of U. It can be shown that β, the coefficient of expectations, is given by

$$\beta = \frac{dw}{d-b}.$$

An alternative model in which adaptive expectations are rational is one in which the price consists of two components, again one of which may be considered permanent and the other transitory. This model may be expressed in the form:

$$P_t = \bar{P}_t + \eta_t$$

where $\bar{P}_t$ is the permanent component and η_t is the transitory component:

* I am grateful to referees of this Journal for their helpful comments.

[1] See Cagan [1] and Nerlove [4, 5].

[2] For a proof of this statement and a further discussion of rational expectations, see Muth [3] and Nerlove [6]. Their proof is equivalent to one we use here for the more general model.

VAHID F. NOWSHIRVANI *is assistant professor of economics at Yale University.*

$$E\eta_i = 0 \quad \text{and} \quad E\eta_i\eta_j = \begin{cases} \sigma_\eta^2 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

It is also assumed that

$$\bar{P}_t = \bar{P}_{t-1+\epsilon_t}$$

where ϵ_t is an independent random variable with mean zero and variance σ_ϵ^2. In this case the coefficient of expectation is a function of the relative variances of η and ϵ.[3]

A More General Model

In the models discussed by Muth [3] and Nerlove [5] the disturbance term is confined to the supply equation. This is not a necessary assumption, and a disturbance term can just as well be included in the demand equation. In fact, for the purpose of estimating the supply function, the inclusion of the disturbance term in the demand equation is more satisfactory. Otherwise, since U_t's are serially correlated, problems will arise in the estimation. Disturbance terms can, in fact, be included in both the supply and the demand function. Since the model of price expectation formation which we propose is a special case of this general model, the derivation of the latter is presented below.

Let us assume that both supply and demand functions contain a disturbance term:

$$Q_t^s = a + bP_t^* + U_t \tag{1}$$

$$Q_t^d = c + dP_t + V_t \tag{2}$$

If the variables are defined as deviations from their equilibrium values,[4] then

$$Q_t^s = bP_t^* + U_t$$

$$Q_t^d = dP_t + V_t.$$

From the market-clearing equation in each period we have

$$Q_t^d = Q_t^s. \tag{3}$$

It follows that

$$P_t = \frac{b}{d} P_t^* + \frac{1}{d}(U_t - V_t). \tag{4}$$

We assume that

$$U_t = \epsilon_t + w \sum_{i=1}^{\infty} \epsilon_{t-i} \tag{5}$$

and

$$V_t = \eta_t + x \sum_{i=1}^{\infty} \eta_{t-i} \tag{6}$$

where ϵ and η are independently distributed random variables with mean zero and variance σ_ϵ^2 and σ_η^2, respectively, and x and w are constants with absolute value less than one. Notice that if $x = w = 0$, i.e., if U_t and V_t are serially independent, there will be no tendency to change the expectation of the price. (This can easily be verified by examining equation (9)). Substituting for U_t and V_t, we get

$$P_t = \frac{b}{d} P_t^* + \frac{1}{d}\left(\epsilon_t - \eta_t + w \sum_{i=1}^{\infty} \epsilon_{t-i} - x \sum_{i=1}^{\infty} \eta_{t-i}\right). \tag{7}$$

For rational expectations,

$$E(P_t) = P_t^*. \tag{8}$$

Taking the expected value of (7) and using equation (8), we obtain

$$P_t^* = \frac{b}{d} P_t^* + \frac{1}{d}\left(w \sum_{i=1}^{\infty} \epsilon_{t-i} - x \sum_{i=1}^{\infty} \eta_{t-i}\right)$$

since $E\epsilon_t = E\eta_t = 0$.[5] Solving for P_t^* gives

$$P_t^* = \frac{1}{d-b}\left(w \sum_{i=1}^{\infty} \epsilon_{t-i} - x \sum_{i=1}^{\infty} \eta_{t-i}\right). \tag{9}$$

Substituting for P_t^* in (7), we get

$$\begin{aligned} P_t = {} & \frac{b}{d}\frac{1}{d-b}\left(w \sum_{i=1}^{\infty} \epsilon_{t-i} - x \sum_{i=1}^{\infty} \eta_{t-i}\right) \\ & + \frac{1}{d}\left(\epsilon_t - \eta_t + w \sum_{i=1}^{\infty} \epsilon_{t-1} - x \sum_{i=1}^{\infty} \eta_{t-i}\right). \end{aligned} \tag{10}$$

Therefore

$$\begin{aligned} P_t = {} & \frac{1}{d}(\epsilon_t - \eta_t) \\ & + \frac{1}{d-b}\left(w \sum_{i=1}^{\infty} \epsilon_{t-i} - x \sum_{i=1}^{\infty} \eta_{t-i}\right). \end{aligned} \tag{11}$$

Substituting equation (9) in equation (11), we have

[3] For a proof of this assertion, see Muth [2].

[4] The equilibrium values of P and Q may be obtained by setting $U_t = V_t = 0$, $P_t^* = P_t = \bar{P}$ and $Q_t^s = Q_t^d) = \bar{Q}_t$.

[5] The expected value of P_t is for given values of ϵ_{t-i} and η_{t-i}, $i = 1, 2 \cdots \infty$.

$$P_t = \frac{1}{d}(\epsilon_t - \eta_t) + P_t^*,$$

from which it follows that

$$(\epsilon_t - \eta_t) = d(P_t - P_t^*).$$

Therefore

$$(12) \quad (\epsilon_{t-i} - \eta_{t-i}) = d(P_{t-i} - P_{t-i}^*).$$

Lagging equation (9) by one period, it is clear that

$$(13) \quad P_{t-1}^* = P_t^* - \frac{1}{d-b}(w\epsilon_{t-1} - x\eta_{t-1}).$$

If $w=x$ or if either η_{t-1} or $\epsilon_{t-1}=0$, which implies that either the supply or the demand equation does not include a random disturbance, we can substitute equation (12) in equation (13) to get

$$P_{t-1}^* = P_t^* - \frac{dw}{d-b}(P_{t-1} - P_{t-1}^*).$$

Therefore

$$(14) \quad P_{t-1}^* = P_{t-1}^* = \frac{dw}{d-b}(P_{t-1} - P_{t-1}^*),$$

which is the adaptive expectations model with $\beta = dw/(d-b)$.

Equation (14) rather than equation (9) is generally used to represent the expectation of price, because ϵ_t and η_t are usually unobservable and cannot be directly substituted in equation (9). However, this need not always be the case. For instance, if the disturbance in the supply function is caused by weather we may have a direct observation of ϵ_t. It is reasonable to assume that farmers generally have some idea as to the state of harvest in any year, and it may be possible to incorporate this information about supply situations directly in the price expectation formulas rather than to rely solely on past prices. Furthermore, in some situations it may be possible to form a rational expectation of prices that is a function only of past prices. A model in which this may be the case is now examined.

A Special Case

It is assumed that the model is the same as the general model, except that the disturbance in the supply equation is given by

$$U_t = \epsilon_t.$$

$$E\epsilon_t = 0 \qquad E\epsilon_i\epsilon_j = \begin{cases} \sigma^2 & \text{if } i = j \\ 0 & \text{if } i \neq j \end{cases}$$

Here we are assuming that the U_t's are not serially correlated, a reasonable hypothesis if U_t is primarily due to variations in weather. Following exactly the same procedure as before, we get

$$(15) \quad \epsilon_{t-i} - \eta_{t-i} = d(P_{t-i}^* - P_{t-i}^*).$$

But since in this case $w=0$, equation (13) now becomes

$$(16) \quad P_{t-1}^* = P_t^* + \frac{x}{d-b}\eta_{t-1}.$$

Substituting for η_{t-1} in (16), we have

$$P_{t-1}^* = P_t^* - \frac{x}{d-b}d(P_{t-1} - P_{t-1}^*) + \frac{x}{d-b}\epsilon_{t-1}.$$

$$(17) \quad P_t^* - P_{t-1}^* = \frac{dx}{d-b}(P_{t-1} - P_{t-1}^*) - \frac{x}{d-b}\epsilon_{t-1}.$$

As we can see from equation (17), rational expectations in this model are a modified form of adaptive expectations.

The form of equation (17) is quite reasonable on intuitive grounds. One would expect farmer's reactions to price changes to depend on harvest conditions. If in the past they have observed a certain correlation between price and harvest conditions, they would try to discount that part of the price which they believe to be caused by an abnormality in supply. Since price changes can be due to disturbances in either supply or demand, the price expectation model has two parts, one to account for changes in the former and the other for adjusting to the latter.

For estimation purposes we must substitute for ϵ_{t-1} an observable variable. One which suggests itself most readily is the difference between the actual and the expected yield. Thus,

$$P_t^* - P_{t-1}^* = \beta(P_{t-1} - P_{t-1}^*) + \delta(Y_{t-1} - Y_{t-1}),$$

where Y_{t-1} is the average per acre yield in period $t-1$ and Y_{t-1}^* is the expected yield which can be independently estimated from a time series of yields. The farmers would of course have some notion of normal yields. The model would be most appropriate in a relatively small geographical area in which we can rea-

sonably assume that the farmers are aware of the harvest conditions for the entire region. For larger markets various agricultural information services could replace the more intimate personal knowledge of the state of harvest.

Finally a word of warning about the use of the above price expectation model and, in general, other rational expectations models. First, empirically estimated supply functions often contain price ratios rather than absolute prices. It is argued that the underlying structure is similar to the general model presented earlier; it follows that the same price deflator is used in both the demand and supply equations. This may not be appropriate in some situations.

The second point concerns dynamic supply response and partial adjustment models.[6] The use of partial adjustment models in conjunction with rational expectations is not very satisfactory, the reason being that, when the demand is less than perfectly elastic, producers' supply response will affect prices. If their price expectations are to be rational, the producers must be aware of the distinction between short-run and long-run supply. If they expect a certain price in a given period, but cannot immediately adjust their supply to this equilibrium value, the actual price will be different from their expected price, which will no longer be rational. Thus the partial adjustment hypothesis is not consistent with the rational expectations hypothesis.

[6] For a discussion of partial adjustment models, see Nerlove [4, 5].

Effects of Misspecifications of Log-Linear Functions When Sample Values are Zero or Negative*

S. R. JOHNSON AND GORDON C. RAUSSER

NONLINEAR FUNCTIONS of the form

$$(1) \qquad y = X_1^{\alpha_1} \cdots X_k^{\alpha_k} e^{\mu}$$

are commonly employed for empirical work in economics. The particular nonlinear functional form is popular principally because of its exhibited properties, which have convenient economic interpretations, and because of its successful application to various types of economic and physical data [1, 3, 5, 7]. Estimation of the parameters for (1) is typically based on a logarithmic transformation. That is, for a sample size n,

$$(2) \qquad \ln y_j = \alpha_1 \ln X_{1j} + , \cdots, + \alpha_k X_{kj} + \mu_j \qquad j = 1, 2, \cdots, n.$$

If the X_i, $i = 1, 2, \cdots, k$, are nonstochastic and of rank k, and if μ is distributed normally with zero mean and finite variance, σ^2, then the least squares estimators, $a_1, a_2, \cdots, a_k$, of the α_i, $i = 1, 2, \cdots, k$, in (2) are maximum likelihood and also best linear unbiased [4, pp. 164–180]. The logarithmic transformation therefore facilitates a convenient computational procedure which results in parameter estimates that have the usual desirable properties.[1]

A common problem in obtaining estimates of the α_i by utilizing the log-linear form occurs when there are zero or negative observations in the sample.[2] The logarithmic transformation for the nonpositive values that exist in the sample is not defined in the real space [8, pp. 48–52]. Hence, the maintained hypothesis is violated and the estimation procedure just described cannot be directly applied.

Three types of modifications or misspecifications of the sample data have been applied to permit estimation of the α_i from the related log-linear form [1, pp. 94–97 and 7, p. 572]. These are: (i) addition of a positive constant to all sample observations so that previously negative values become positive; (ii) replacement of negative or zero values within the sample by small positive constants; and (iii) exclusion of observations that include the nonpositive values from the remainder of the sample. Although these modifications are frequently applied in empirical work, their effects on the resulting parameter estimates are not generally known. For instance, Hu and Tseng [7] have only recently presented experimental results for the special problem of adding constants to positively valued independent variables in a log-linear model as a basis for providing some indication of the effect of such modifications on parameter estimates.

In this discussion we shall first give an analytical solution to the special problem of Hu and Tseng, i.e., the addition of constants to positively valued variables. The solution will then be used to suggest an alternative specification that is consistent with both observed zero or negative values for the X_i and the loglinear functional form. Moreover, for this alternative specification we demonstrate that it is possible to obtain parameter estimates that are consistent and asymptotically more efficient than those obtained by omitting negative-valued observations of the X_i and proceeding with the traditional approach.

Effects of Misspecifications when $X_{ij} > 0$

Consider the simplified version of equation (1):

$$(3) \qquad y = X_1^{\alpha_1} e^{\mu}.$$

* Giannini Foundation Research Paper 312. The authors express their appreciation to D. W. Barnette and M. W. J. Layard for their helpful comments and suggestions on an earlier draft of this manuscript.

[1] Predicted values of y based on estimates from this particular function must be interpreted differently from those estimated in the usual linear case. The required differences in interpretation are indicated by Goldberger [3] and are derived from the discrepancy between the expected value of $\ln y$ and the natural log of the expected value of y. Additional results related to this question have recently been derived by Bradu and Mundlak [2].

[2] Negative or zero values for some of the observations in the sample may occur, for example, in data from controlled experiments for agricultural crops, in family budget studies in which zero expenditures are observed for various types of commodities, and in the differencing and indexing of prices that are sometimes employed in empirically oriented economic studies.

Suppose that α_1 is to be estimated from a sample of size n. Assume a specification error of type (*i*) is introduced prior to the estimation of α_1 from the log-linear form of equation (3). In particular, assume a constant b is added to each value of X_{1j}, $j=1, 2, \cdots, n$. The misspecified equation is then

$$y_j = (X_{1j} + b)^{\alpha_1'} e^{\mu_j'} \tag{4}$$

where primes have been added to denote effects of the alteration in the value of variable $(X_{1j}+b)$ representing X_{1j}.

The least squares estimator of α_1', a_1', is given by

$$a_1' = \frac{\sum_{j=1}^{n} [1n(X_{1j} + b)][1ny_j]}{\sum_{j=1}^{n} [1n(X_{1j} + b)]^2}. \tag{5}$$

Upon substituting the "true" value for $1ny_j$, i.e., $1ny_j = \alpha_1 1nX_{1j} + \mu_j$, and employing an alternative expression for $1n(X_{1j}+b)$, i.e.,

$$1n(X_{1j} + b) = 1nX_{1j} + 1n\left(\frac{X_{1j} + b}{X_{1j}}\right),$$

the expected value of a_i can be shown to be

$$E(a_1') = \alpha_1 - \alpha_1 \tag{6}$$

$$\frac{\sum_{j=1}^{n} [1n(X_{1j} + b)]\left[1n\left(\frac{X_{1j} + b}{X_{1j}}\right)\right]}{\sum_{j=1}^{n} [1n(X_{1j} + b)]^2}.$$

Hence, unless $\alpha_1=0$ or $b=0$ in which case

$$1n\left(\frac{X_{1j} + b}{X_{1j}}\right) = 0,$$

a_1' is a biased estimator of α_1. It follows then that the magnitude of the bias is dependent upon the size of b and can easily be evaluated for specific X_{1j} and conditional values for α_1.

The second type of misspecification turns out to be a special case of the first. Effects of adding constants to selected X_{1j} in the sample can therefore be inferred from (6) by assuming that b is added to only a proper subset of the X_{1j}, say the first $p<n$ of the X_{1j}. It is clear from (6) that the resulting bias is smaller than for the specification of type (*i*).

The last type of misspecification—deleting those p observations that have been augmented by b—produces an unbiased estimator, if the omitted observations are regarded as outliers. However, discarding the information in the p excluded observations may lead to adverse effects on the variance of estimators so obtained. This consideration suggests a comparison of variances for the least squares estimators based on three types of misspecifications. By appropriate manipulation of $E[a_1' - E(a_1')]^2$ for each type of error in specification, the following expressions for sampling variances are derived:

$$\text{(i) Var } (a_1') = \frac{\sigma^2}{\sum_{j=1}^{n} [1n(X_{1j} + b)]^2}$$

$$\text{(ii) Var } (a_1') = \frac{\sigma^2}{\sum_{j=p+1}^{n} [1nX_{1j}]^2 + \sum_{j=1}^{p} [1n(X_{1j} + b)]^2} \tag{7}$$

$$\text{(iii) Var } (a_1') = \frac{\sigma^2}{\sum_{j=p+1}^{n} (1nX_{1j})^2}.$$

From (7) it follows that the variance of a_1', as calculated according to misspecification (iii), is always larger than that for misspecifications (i) or (ii). Hence, the choice among methods appears to depend upon a weighing of the bias against the improvement in efficiency, i.e., the mean square error.[3]

As would be expected, these conclusions are consistent with the results of the sampling experiments reported by Hu and Tseng [7]. However, contrary to the contention of these two authors, the method employed in deriving the results suggests that they have very little bearing on the situation in which some $X_{1j} \leq 0$. This inference follows from the observation that the "true" value for $y_j = \alpha_1 1nX_{1j} + \mu_j$ cannot be evaluated in real terms or, more generally, that the observations for which $X_{1j} \leq 0$ are not consistent with the maintained hypothesis. Hence, only type (iii) of the misspecifications, which in effect treats the nonpositive values of X_{1j} as outliers, is of consequence for the main problem being investigated. If useful conclusions are to be produced regarding the

[3] When these results are generalized to the case in which $1<k<n$, the conclusions remain unchanged. Furthermore, since the expression for the bias is known it is possible to derive a transformation of the data that yields unbiased estimators of the parameters $\alpha_1, \cdots, \alpha_k$.

comparative properties of parameters obtained from three types of misspecifications when $X_{ij} \leq 0$, a maintained hypothesis must be developed that is consistent with the observed data. We turn to this task next.

An Alternative Specification for $X_{1j} \leq 0$

The specification for $X_{1j} \leq 0$ is presented for the two-variable case in equation (8) which represents an alternative maintained hypothesis:

$$(8) \quad y_j = (X_{1j} + b_j)^{\delta_1} e^{\mu_j}; \quad j = 1, 2, \cdots, n,$$

where $b_j = b$, for $j = 1, 2, \cdots, p < n$ and $b_j = 0$ otherwise; $b_j + X_{ij} > 0$ for all j; and the assumed properties continue to hold for the error term e^{μ_j}. For this alternative maintained hypothesis, b can be treated as a parameter; the parameters can be estimated in the context of a logarithmic transformation; and the attributes of the functional form (1) continue to apply.

Least squares estimators of the parameters b and δ_1, denoted $\hat{b}$ and d_1, respectively, are obtained from the log-linear form of equation (8). To demonstrate this result, we first recognize that the restrictions on b_j imply that the n observations can be regarded as two separate samples satisfying the relations:

$$(9) \quad \begin{aligned} 1ny_j &= \delta_{11} 1n(X_{1j} + b) + \mu_j \\ & \qquad j = 1, 2, \cdots, p \quad \text{and} \\ 1ny_j &= \delta_{12} 1n X_{1j} + \mu_j \\ & \qquad i = p + 1, \cdots, n. \end{aligned}$$

The estimation problem is to find $\hat{b}$, d_{11}, and d_{12}, such that the sum of squares is minimized subject to the conditions that $\delta_{11} = \delta_{12}$ and $1n(X_{1j} + \hat{b}_j)$ is a real number for all j. Assuming that the latter constraint is implicitly satisfied,[4] the parameter estimators are obtained from the first order conditions for the Lagrangian:

$$(10) \quad \begin{aligned} L(\delta_{11}, \delta_{12}, b, \lambda) \\ &= \sum_{j=1}^{p} [1ny_j - \delta_{11} 1n(X_{1j} + b)]^2 \\ &\quad + \sum_{j=p+1}^{n} [1ny_j - \delta_{12} 1n X_{1j}]^2 \\ &\quad + 2\lambda(\delta_{11} - \delta_{12}). \end{aligned}$$

First order conditions $\partial L/\partial \delta_{11}$, $\partial L/\partial \delta_{12}$, and $\partial L/\partial \lambda$ are combined to give an expression for d_1:

$$(11) \quad d_1 = d_{12} = d_{11} = \frac{\sum_{j=1}^{p} 1ny_j 1n(X_{1j} + \hat{b}) + \sum_{j=p+1}^{n} 1ny_j 1n X_{1j}}{\sum_{j=1}^{p} [1n(X_{1j} + \hat{b})]^2 + \sum_{j=p+1}^{n} [1n X_{1j}]^2}.$$

The estimator in equation (11) indicates that once $\hat{b}$ is known d_1 can be derived by direct application of log-linear methods to the resulting sample data. The partial derivative of the Lagrangian with respect to b, together with equation (11), is used to solve for $\hat{b}$. That is, $\hat{b}$ is obtained from

$$(12) \quad \sum_{j=1}^{p} \frac{1}{X_{1j} + \hat{b}} [1ny_j - d_1 1n(X_{1j} + \hat{b})] = 0.$$

Solution of equation (12) for $\hat{b}$ turns out to be rather complex; hence, we consider the simplified problem $X_{1j} \leq 0$, $j = 1, 2, \cdots, p$, all of the same value, before attempting a more general solution for $\hat{b}$.[5] For $X_{1j} + \hat{b}$, $j = 1, 2, \cdots, p$ a constant the term $1/(X_{1j} + \hat{b})$ can be eliminated from (12) by division. Thus, on substituting for d_1 from (11), obtaining a common denominator, and taking the sum over p, it follows from (12) that $1n(X_{1j} + \hat{b})$, $j = 1, 2, \cdots, p$, is

$$(13) \quad 1n(X_{1j} + \hat{b}) = \frac{\sum_{j=p+1}^{n} [1n X_{1j}]^2}{\sum_{j=p+1}^{n} 1ny_j 1n X_{1j}} \cdot \frac{\sum_{j=1}^{p} 1ny_j}{p};$$

that is, $1n(X_{1j} + \hat{b})$ is the inverse of the regression coefficient obtained from the data for which $X_{1j} > 0$ multiplied by the mean of the $1ny_j$ corresponding to the $X_1 \leq 0$. Hence, for this simplified case, $\hat{b}$ puts the mean of the logged values for y_j, $j = 1, 2, \cdots, p$ on the regression surface as calculated from the $p+1, \cdots, n$ observations satisfying the maintained hypothesis for (3).

[4] The parameter b turns out to take on a value which places the $1ny_j$, $j = 1, 2, \cdots, p$ near the regression line calculated from the data for which $X_{1j} > 0$. An exception may occur when there is wide dispersion in the $X_{1j} \leq 0$. However, for analytical convenience, the assumption that $1n(X_{1j} + \hat{b}_i)$ is real number for all j will be maintained.

[5] This situation is not as special as it at first may appear. For example, it would be applicable in budget studies in which zero expenditures are reported and in response function estimates for agricultural crops that are based on experimental data containing zero control levels for some or all factors.

The generalization to $X_{1j} \leq 0$ (not all of the same value) requires two approximations if the nonlineality implicit in expression (12) is to be avoided. In particular, for sufficiency small variation in the X_{1j}, $j=1, 2, \cdots, p$, $X_{1j}+b$ in (12) can be regarded as a constant.[6] In addition, from a Taylors Series Expansion of $1n(X_{1j}+b)-1n(X_{1j}-\hat{b})$ about 1 it can be shown that deviations from $1n(X_{1j}-\hat{b})$ are approximated by $X_{1j}-\overline{X}_1$.[7] If we denote $X_{1j}-\overline{X}$ as ξ_j and substitute these approximations into (12), the resulting estimator of b, $\hat{b}$ is given by $\overline{X}_1$ and the numerical value for the antilog of

$$1n\overline{(X_{1j}+b)} = \frac{\dfrac{p\sigma_\xi^2 + \sum_{j=p+1}^{n} [1nX_{1j}]^2}{\sum_{j=1}^{p} 1ny_j\xi_j + \sum_{j=p+1}^{n} 1ny_j 1nX_{1j}}\sum_{j=1}^{p} 1ny_j}{p}. \tag{14}$$

As indicated above, the approximation is good only when X_{1j}, $j=1, 2, \cdots, p$ are in close proximity. In the event that these conditions are not met, the estimator of b can be improved by iterating the computation of $1n\overline{(X_{1j}+\hat{b})}$ in equation (14).

Since d_1 and b, aside from the problems of approximation mentioned above, are also maximum likelihood estimators, it follows that they are asymptomatically unbiased and efficient.[8] The asymptotic expression for the variance of d_1 is easily derived from (11) and is identical with (ii) in (7).[9] Thus, conclusions similar to those obtained earlier apply. The asymptotic variance of d_1 is clearly smaller than that for a_1' in the situation in which the p sample values corresponding to $X_{1j} \leq 0$ are excluded. Hence, if d_1 and a_1' are similar, the procedure just derived appears to be the better of the two alternatives.

Extension of these results to the situation in which $k>1$ presents further nonlinearity problems. However, under the approximating assumptions employed thus far, the computational task remains manageable. To illustrate, consider the case in which ith X_{ij} has $j=1, 2, \cdots, p$ identical nonpositive values. Let X denote the matrix of n observations on the k independent variables. For purposes of convenience, X is written as

$$X = \begin{bmatrix} X_1 & 0 \\ 0 & X_2 \end{bmatrix},$$

where X_1 contains the first p of the observations and X_2 contains observations $p+1, \cdots, n$. The vector of observations on the dependent variable $y=(y_1, y_2)'$ is similarly partitioned. With $\delta=(\delta_1, \delta_2)'$ defined as the $2k$ vector of parameters and μ as the error vector, the model to be estimated can be written $y=X\delta+\mu$.

Proceeding as in the two-variable problem, we set up the Lagrangian for the partitioned sample data:

$$L(\delta_1, \delta_2, \lambda, b) = (y - X\delta)'(y - X\delta) - 2\lambda'(\delta_1 - \delta_2). \tag{15}$$

First order conditions for maximizing the Lagrangian can be combined to demonstrate that the least squares estimator of δ_1 and δ_2 is $d_1=d_2=(X_1'X_1+X_2'X_2)^{-1}(X_1'y_1+X_2'y_2)$. The partial derivative with respect to λ is given by

$$1(y_1 - X_1d_1) = 1(\hat{u}_1) = 0 \tag{16}$$

where 1 is the sum vector and $\hat{u}_1$ denotes the vector of least squares residuals. Substitution for d_1 produces an expression that is a polynomial in $\hat{b}$.[10] However, the form of equation (16) suggests an easy computational procedure for approximating $1n(X_{ij}+\hat{b})$: Simply substitute the estimator of δ_2 from the part of the

[6] This approximation is required to avoid severe difficulties with nonlinearities. In the event that the dispersion among the X_{1j}, $j=1, 2, \cdots, p$ is large enough that the approximation is not appropriate the problem can be handled by partitioning the $X_{1j} \leq 0$ into two groups and estimating a constant for each.

[7] $$1n(X_{1j}+b) \approx \frac{X_{1j}+b-1}{1} = (X_{1j}-\overline{X}_1)+(\overline{X}_1+b-1)$$

and

$$1n\overline{(X_{1j}+b)} \approx \frac{1}{p} \sum (X_{1j} - \overline{X}_1)+(\overline{X}_1+b-1).$$

Therefore $1n(X_{1j}+b)-1n(X_{1j}+b) \approx X_{1j}-X_1$.

[8] For a derivation of the maximum likelihood estimation results see Goldberger [4, pp. 207–212].

[9] Since b is consistently estimated by (13) or (14), it follows by using Slutsky's theorem regarding asymptotic expectations of products of random variables [4, p. 270] that the variance can be directly derived from (11).

[10] The exact expression for is given b$\hat{b}$y $1(y_1-[I-X_1(X_2'X_2)^{-1}X_1'] [X_1'\delta_2+X_1'(X_2'X_2)^{-1}X_1'y_1]$, where δ_2 is the least squares estimate of δ_2 from X_2. Since the ith column of X_1 contains the constant value $\ln(X_{ij}+\hat{b})$, the expression is polynomial in $\ln(X_{ij}+\hat{b})$.

data contained in y_2 and X_2, $\underline{d}_2$ into equation (16). Denoting the elements of $\underline{d}_2$ as $\underline{d}_{21}$, $\underline{d}_{22}$, $\cdots$, $\underline{d}_{2k}$ and the means of the columns of X_2 as $\overline{1nX}_{21}$, $\overline{1nX}_{22}$, $\cdots$, $1n(X_i+\hat{b})$, $\cdots$, $\overline{1nX}_{2k}$, the approximate value of $1n(X_i+\hat{b})$ from (16) and $\underline{d}_2$ is

$$\begin{aligned}1n(X_i + \hat{b}) = \underline{d}_{2i}^{-1}[\overline{1ny} - (&\underline{d}_{21}\overline{1nX}_{21} \\ &+ \cdots + \underline{d}_{2i-1}\overline{1nX}_{2i} \\ &+ \underline{d}_{2i+1}\overline{1nX}_{2i+1} \\ &+ \cdots + \underline{d}_{2k}\overline{1nX}_{2k})].\end{aligned} \tag{17}$$

On substituting the approximated value for $1n(X_i+\hat{b})$ into the sample data, estimating the parameters from the full-data set, and then repeating the above procedure (i.e., iterating until a satisfactory indication of convergence has been achieved), the least squares estimator for $1n(X_i+\hat{b})$ can be obtained. Hence, although direct solution for the parameter indicating the distance by which the $X_{ij}\leq 0$ are to be moved into the positive orthant presents some computational problems, the numerical procedure for approximating it is quite straightforward. Furthermore, apart from the possibility of multiple stationary values for (15) in $1n(X_1+\hat{b})$, the similarity of (17) to (13) suggests that the approximating procedure should give a satisfactory value for $1n(X_i+\hat{b})$ in a relatively small number of iterations.

Conclusions

The applicability of a multiplicative functional form and the related log-linear estimation procedure is admittedly a precarious approach when sample data include negative or zero values in some of the observations on the independent variables. The hazards result largely from the inconsistency of the observed sample information with a maintained hypothesis of the type mentioned in connection with equation (1). In this paper we have indicated the limitations associated with the traditional log-linear functional form and have provided an alternative log-linear form within the context of which negative values for the X_{ij} can be treated. Although the alternative log-linear form provides estimates that are only asymptotically unbiased and efficient, the nature of the expressions for b would indicate that improvements in efficiency occur for relatively small sample sizes and relatively small proportions of the $X_{ij}\leq 0$.

A Model for Agricultural Policy: An Addendum

Micha Gisser

In two previous articles I have developed a model of the farm labor market [1, 2]. One of the basic assumptions underlying this model was that capital is exogenous to the farm labor market. Geometrically this assumption boils down to a vertical supply curve whose shift, right or left, is determined by economic forces outside the farm sector. This model will be known here as Model A. Utilizing some accepted econometric estimates, I obtained estimates for parameters appearing in the two reduced equations for farm labor.

In this addendum I replace the assumption of a vertical supply curve by a different assumption according to which the farm sector is confronted with a horizontal supply curve of capital. In other words, the farm sector has no influence over the cost of capital which is the exogenous variable. This model will be known as Model B. My main purpose is to compare the empirical estimates obtained by using the two different models. In addition to comparison per se, Model B yields a by-product: It enables us to examine the effects of a change in the price of capital on returns to farm labor and farm employment.

The Two Models

A by-product of this paper is an improved notation over that employed in the prior papers. The earlier notation could confuse an unwary reader. Equation (5) in [1] is called the "demand for labor," which is not a very apt definition of marginal physical product. The symbols a_2 and a_3 have one meaning in equations (1) and (3) and another meaning in equation (8) [1, p. 809]. This could have been avoided by writing equation (1) as $W_d^* = v_1 + v_2 L + v_3 C$ and then, after equation (8) was derived, let

$$v_1 = \left[1 + a_2 - \frac{H}{\eta} + \left(1 + \frac{1}{\eta}\right)K\right],$$

$$v_2 = \left[a_2\left(1 + \frac{1}{\eta}\right) + \frac{1}{\eta}\right]$$

and

$$v_3 = \left[a_3\left(1 + \frac{1}{\eta}\right)\right].$$

In order to avoid this confusion, instead of starting with a demand and supply of farm labor, I start now with the final output sector and derive from it the demand for farm labor.

As in my earlier articles, to keep the presentation in manageable proportions all variables are expressed in logarithms. The final output sector can be described as follows:

(1) Production function:

$$Q = K + (1 + a_2)L + a_3 C$$

(2) Marginal physical product of labor:

$$W_d = K + (1 + a_2) + a_2 L + a_3 C$$

(3) Marginal physical product of capital:

$$I_d = K + a_3 + (1 + a_2)L + (a_3 - 1)C$$

(4) Value marginal product of labor:

$$W_d^* = W_d + P$$

(5) Value marginal product of capital:

$$I_d^* = I_d + P$$

(6) Demand for final output:

$$P = \frac{1}{\eta}Q - \frac{H}{\eta}$$

where Q, K, L, C, W_d, I_d, W_d^*, I_d^*, P, η, and H stand for agricultural output, the shift in the production function, labor, capital, marginal physical product of labor, marginal physical product of capital, the value of marginal physical product of labor, the value of marginal physical product of capital, price of final output, price elasticity of final output, and the horizontal shift in the demand for output, respectively. By substituting the right side of (2) for W_d in (4), the right side of (1) for Q in (6), and the right side of (6) for P in (4), we obtain the (adjusted) demand function for labor:

$$W_d^* = 1 + a_2 + \left[a_2\left(1 + \frac{1}{\eta}\right) + \frac{1}{\eta}\right]L + a_3\left(1 + \frac{1}{\eta}\right)C - \frac{H}{\eta} \qquad (7)$$

Micha Gisser *is associate professor of economics at the University of New Mexico.*

$$+\left(1+\frac{1}{\eta}\right)K.$$

The supply function of labor is

$$W_s^* = -b_2b_1 + b_2L \tag{8}$$

where b_1 reflects the horizontal shift in the supply of labor. Note that (unlike in the earlier articles) the wage rate is denoted by W_s^* rather than W_s, because the supply price is set equal to VMP, not to marginal physical product.

A procedure similar to the one used to obtain relation (7) yields the adjusted demand function for capital:

$$\begin{aligned} I_d^* = a_3 &+ \left[a_2\left(1+\frac{1}{\eta}\right)+\left(1+\frac{1}{\eta}\right)\right]L \\ &+ \left[a_3\left(1+\frac{1}{\eta}\right)-1\right]C - \frac{H}{\eta} \\ &+ \left(1+\frac{1}{\eta}\right)\cdot K. \end{aligned} \tag{9}$$

Notice that a supply function of capital is not introduced because of the assumption that the price of capital is an exogenous variable. Formally this can be written as I_s = constant, and in equilibrium $I_s = I_d^* = I^*$.

Model A

Reducing equations (7) and (8) yields the two reduced forms of Model A:

$$\begin{aligned} W^* = \alpha &- \frac{b_2}{D\eta}H + \frac{b_2\left(1+\frac{1}{\eta}\right)}{D}K \\ &+ \frac{a_3\left(1+\frac{1}{\eta}\right)b_2}{D}C \\ &+ \frac{\left[a_2\left(1+\frac{1}{\eta}\right)+\frac{1}{\eta}\right]b_2}{D}b_1 \end{aligned} \tag{10}$$

$$\begin{aligned} L = \beta &- \frac{1}{D\cdot\eta}H + \frac{\left(1+\frac{1}{\eta}\right)}{D}K \\ &+ \frac{a_3\left(1+\frac{1}{\eta}\right)}{D}C + \frac{b_2}{D}b_1 \end{aligned} \tag{11}$$

where α and β are constants and

$$D = b_2 - \left[a_2\left(1+\frac{1}{\eta}\right)+\frac{1}{\eta}\right].$$

Model B

Equations (7), (8), and (9) can be written, using matrix notations, as follows:

$$\begin{bmatrix} -1 & \left[a_2\left(1+\frac{1}{\eta}\right)+\frac{1}{\eta}\right] & a_3\left(1+\frac{1}{\eta}\right) \\ -1 & b_2 & 0 \\ 0 & \left[a_2\left(1+\frac{1}{\eta}\right)+\left(1+\frac{1}{\eta}\right)\right] & \left[a_3\left(1+\frac{1}{\eta}\right)-1\right] \end{bmatrix} \begin{bmatrix} W^* \\ L \\ C \end{bmatrix} = \begin{bmatrix} \frac{1}{\eta}H - \left(1+\frac{1}{\eta}\right)K - (1+a_2 \\ b_2b_1 \\ I^* + \frac{1}{\eta}H - \left(1+\frac{1}{\eta}\right)K - a \end{bmatrix} \tag{12}$$

Reducing equation (12) yields the followin three reduced forms:

$$\begin{aligned} W^* = \gamma &- \frac{b_2}{\Delta\eta}H + \frac{\left(1+\frac{1}{\eta}\right)b_2}{\Delta}K \\ &- \frac{a_3\left(1+\frac{1}{\eta}\right)b_2}{\Delta}I^* \end{aligned} \tag{13}$$

$$+\frac{\left[\left(1+\frac{1}{\eta}\right)(a_2+a_3)+\frac{1}{\eta}\right]b_2}{\Delta}b_1$$

$$L=\kappa-\frac{1}{\Delta\eta}H+\frac{1+\dfrac{1}{\eta}}{\Delta}K$$

$$-\frac{a_3\left(1+\dfrac{1}{\eta}\right)}{\Delta}I^* \tag{14}$$

$$+\frac{\left[1-a_3\left(1+\dfrac{1}{\eta}\right)\right]b_2}{\Delta}b_1$$

$$C=\lambda-\frac{1+b_2}{\Delta\eta}H$$

$$+\frac{(1+b_2)\left(1+\dfrac{1}{\eta}\right)}{\Delta}K$$

$$+\frac{\left[a_2\left(1+\dfrac{1}{\eta}\right)+\dfrac{1}{\eta}-b_2\right]}{\Delta}I^* \tag{15}$$

$$+\frac{\left(1+\dfrac{1}{\eta}\right)(1+a_2)b_2}{\Delta}b_1$$

vhere Δ is the determinant of the matrix which s premultiplied by the vector (W^*LC) in the et (12), and γ, κ and λ are constants.

Comparison of Empirical Estimates: Model A versus Model B

The econometric estimates of the parameters .ppearing in both models are summarized in 'able 1.

[able 1. Econometric estimates of parameters

Parameter	Symbol	Value
rice elasticity of demand for output	η	−0.25, −0.50
oefficient of labor in the production function	$1+a_2$	0.50
oefficient of capital in the production function	a_3	0.30
eciprocal of supply elasticity of labor	b_2	0.30, 1.00

'he comparison of parameter values is carried ut in Table 2.

The coefficients of H, K, and b_1 for reduced equations of wages and labor, have the same sign in Model A and Model B. This is expected since Model B is a generalization of Model A. The coefficient of I^*, the price of capital in Model B, has the opposite sign of the coefficient of C, capital in Model A. This is hardly suprising for a model employing the price of capital versus a model employing the quantity of capital. Thus, the qualitative results reported in [2] do not change under Model B.

In this paper, as in the earlier articles, capital does not include land. The estimates of capital coefficients are based on studies by Griliches [4] and myself [3]. The estimate of a_3 is intended to provide an order of magnitude rather than a precise statistical measurement. The attention of the reader is called to the fact that in an earlier paper [1, p. 812] farm property, including land, was used in estimating the capital growth rate. This was dictated by data limitation.

The coefficients of b_1, the shift in supply of farm labor, are almost identical for wages and labor in the two models. Hence, the results reported in [1] remain unchanged under Model B.

Finally, if we select the version $b_2=0.30$, $\eta=-0.25$ under Model B, a subsidy on capital leading to a 10 percent reduction in the cost of capital to farmers will result in 0.7 percent reduction in farm wages, 2.3 percent reduction in farm employment, and 7.1 percent increase in the use of farm capital.

To illustrate that Model B is in effect a generalization of Model A, note that if we are *given* a 7.1 percent increase in the use of farm capital, then we are back in Model A. Using Table 2 for Model A, $b_2=0.30$ and $\eta=-0.25$, we find a corresponding percentage change of -0.7 percent in wages and -2.3 percent in farm employment, which checks with the changes presented for Model B.

For the same version under Model B, a 10 percent rightward shift in the demand for farm output will result in 3 percent increase in farm wages, 10.1 percent increase in farm labor use, and 13.1 percent increase in capital.

Under Model A, the corresponding condition would be to combine a 10 percent rightward shift in the demand for farm output with 13.1 percent increase in capital. The results are:

(a) Percentage change in farm wages

$$0.43\times 10\text{ percent}-0.10\times 13.1\text{ percent}$$
$$=3.0\text{ percent}$$

Table 2. Values of coefficients of reduced forms appearing in Model A and Model B

Value of b_2	Endogenous variable	Model	Coefficients of: H A shift in the demand for farm output	K A shift in the production function	Capital: C Farm capital	Capital: r^* Price of farm capital	b_1 A shift in the supply of farm labor
					$\eta=-0.25$		
0.30	W	A	0.43	−0.32	−0.10		−0.27
	W	B	0.30	−0.23		0.07	−0.26
	L	A	1.43	−1.07	−0.32		0.11
	L	B	1.01	−0.76		0.23	0.14
	C	B	1.31	−0.98		−0.71	−0.11
1.00	W	A	1.14	−0.86	−0.26		−0.71
	W	B	0.76	−0.57		0.17	−0.64
	L	A	1.14	−0.86	−0.26		0.29
	L	B	0.76	−0.57		0.17	0.36
	C	B	1.51	−1.13		−0.66	−0.28
					$\eta=-0.50$		
0.30	W	A	0.33	−0.17	−0.05		−0.25
	W	B	0.27	−0.14		0.04	−0.25
	L	A	1.11	−0.56	−0.17		0.17
	L	B	0.91	−0.46		0.14	0.18
	C	B	1.19	−0.59		−0.82	−0.07
1.00	W	A	0.80	−0.40	−0.12		−0.60
	W	B	0.64	−0.32		0.10	−0.58
	L	A	0.80	−0.40	−0.12		0.40
	L	B	0.65	−0.32		0.10	0.42
	C	B	1.29	−0.65		−0.81	−0.16

(b) Percentage change in farm labor

$$1.43 \times 10 \text{ percent} - 0.32 \times 13.1 \text{ percent} = 10.1 \text{ percent}$$

Again, these results check with changes presented for Model B.

In summary, the conclusion that *qualitative results do not change under Model B* might miss the point that the *quantitative results should be identical for corresponding conditions*. As illustrated above, obtaining corresponding conditions involves changing capital under Model A to adjust to a change in capital indicated by Model B.

Returns to Human and Research Capital in the Non-South Agricultural Sector of the United States, 1949–1964*

GIDEON FISHELSON

ALTHOUGH FARM FAMILIES constitute a small fraction of all United States families, they account for much of the observed poverty [14]. Farm income is the sum of the returns to physical capital (land, buildings, machinery), to physical family labor, and to human capital. Hence, one of the reasons for the relatively high percentage of farm families in the low income group might be their small stock of human capital. The research reported here attempts to answer the question whether more public investment in human capital employed in agriculture would be profitable. The answer is reached through the estimation of the rate of return to human capital in the agricultural sector.

To make the study manageable, investment in human capital was restricted to public expenditure on (1) formal education (schooling) of farm operators and (2) nonformal education (extension and vocational education). Highly important by-products of the estimation procedure are the estimates of the returns to other inputs employed, especially public investment in research.

The Model, Variables, and Results

The marginal product of human capital was calculated through the estimation of a farm production function. The function estimated was an exponential one. The unit of observation was the "average" farm in each state in the years 1949, 1954, 1959, and 1964. Together with the conventional inputs (land, labor, machinery, fertilizers, and cash expenditures), three intangible capital inputs were included: (1) the per operator stock of human capital produced by schooling, (2) the per farm stock of human capital produced through extension and vocational training, and (3) the per farm stock of research capital.

The operational definitions of the stocks of human and research capital differ in three ways from their definitions in other studies that investigate the returns to these stocks in the agricultural sector:

(1) Total current public expenditure per pupil in rural areas during the operator's school years was used as a proxy variable for human capital produced by schooling. The use of this operational definition as a proxy variable for human capital assigns different stocks of human capital to operators who completed the same number of years of school at different periods or in different states, even if the number of days of attendance was the same—implying that a year of schooling is not a homogeneous unit of measurement.[1]

(2) The distributed lag function employed for transferring investments in research to research capital utilized in production was based on the rate of adoption of an agricultural innovation—hybrid corn in the corn belt states [5]. (Compare with [1, 6, 15].)

(3) The geographical borders for the relevant investments in research capital were expanded from a state to a production region [6, 15].

The common characteristic of the three stocks is that they were measured by their cost of production. Yet, by employing total per operator public expenditure on schooling as a proxy of the stock of human capital produced by schooling, two components of the cost of production were omitted. The first is income foregone; the second, private expenditure incurred during schooling. In the case of up to eight years of schooling, however, it is proposed that income foregone be disregarded [13], while private direct expenditure incurred for schooling at the elementary and secondary levels is shown to be small relative to public expenditure [8]. Human capital produced by extension and vocational education was approximated by the expenditures on those activities per farm, lagging them by the sequence 0, .3, .5, and .2 for the years t, $t-1$, $t-2$, and $t-3$, respectively.[2]

* This research note is based on a section of my Ph.D. thesis [2]. I am indebted to Dr. L. Ihnen for his close guidance while I was working on my thesis and to the anonymous reviewers whose comments guided me in revising a previous draft of this paper.

GIDEON FISHELSON *is lecturer in economics at Tel-Aviv University, Israel.*

[1] Griliches [6] assumed constant quality of a year of schooling over states and over time and slightly different qualities for different years of schooling. An assumption of overall homogeneity (over states, time, and years of schooling) was implicitly made when the number of years of school completed was used as the schooling input in [3, 9, 10, 15].

[2] The adult vocational agricultural education variable

Research capital per farm was defined as total public expenditure on research in the production region within which the farm is located divided by the number of farms in the corresponding state, lagging it by the sequence 0, .003, .004, .010, .021, .043, .083, .139, .189, .190, .144, .087, .045, .022, .010, .006, and .004 for the years t to $t-16$ respectively.[3]

Several attempts to estimate the production function for the whole United States yielded questionable results. These unsatisfactory results may be due to the difficulty of measuring human capital in the South.[4] The results of estimating the production function for the non-southern states resulted in positive but insignificant coefficients of the three stock variables and a nonsignificant increase in the coefficient of determination (R^2) when tested against an estimate not including those variables. The presence of insignificant coefficients accompanied by high simple correlations among the explanatory variables suggested the possibility of multicolinearity (the correlation between human capital produced by schooling and cash expenditures per farm (.88) was close to the regression multiple correlation coefficient (.98)). Thus, it was decided to utilize prior information when analyzing the production function. This information—the equality of the share of the variable inputs (cash expenditures and machinery cost) to their elasticity of production—was imposed on the estimated relations. Although the significance of the human capital coefficients have been improved (the t values became 1.82 and 1.84 for schooling and for extension and vocational education, respectively), research stayed insignificant (t is 1.13). The inclusion of time dummy variables, while hardly affecting the coefficients and significance of the material inputs, lowered by more than 50 percent the coefficients of the three additional variables, causing them to become en tirely insignificant ($t<1.0$). The apparen reason for these changes is the high positive cor relations between time and each of those vari ables. The time effect between 1949 and 196 is found to be significant (the 1964 coefficient i .042 with a t value of 2.3) even at the presenc of the human and research capital variables implying that productivity not accounted fo by formal and informal education and researcl increased at that period by 11 percent ($10^{.042}$).

The VMP's of the material inputs are of ver reasonable magnitudes (land, .13 dollars pe dollar per year; labor, 11.4 dollars per day; an fertilizers, 614.0 dollars per ton of weighte plant nutrients). The VMP's of the human an research capital variables, although insignifi cant, are high (schooling, .25 dollars per dollar o stock per year; extension and vocational educa tion, 6.0 dollars per dollar of utilized capita stock; research, 12.6 dollars per dollar of uti lized capital stock). The estimated correspond ing internal rates of return to the investment are: to schooling, 9.6 percent when assumin that the returns occur between the ages 25 t 65 and 25 percent if between the ages 15 to 65 to extension and vocational education, 19 percent, and if adjusting as Griliches [6], 2 percent; to research, 39 percent, and if adjustin as Griliches [6], 11 percent.

A comparison of these estimates of th internal rates of return to schooling with thos reported by Hansen [8] and Hanoch [7] indi cates that their estimates for the range of 0–4 t 12 years of schooling were close to the margina rates estimated in this study. The rate reporte by Hansen is 13.6 percent; by Hanoch, 33. and 18.0 percent for northern Whites and non Whites, respectively. The return to researc (unadjusted) is also very close to those esti mated by Griliches [5] for hybrid corn; b Schultz [13] for the whole United States agri culture; and by Mansfield [11] for various in dustries. With regard to extension service there is no other study to refer to. However given the relatively high rate of return to forma schooling, the estimated very high rates of re turn to specific education are not entirely un expected.

Conclusions and Reservations

The methodological and empirical advantag of the employment of a production functio model for measurements of returns to thes investments stems from its direct bridging be

---

was disregarded in [6] and [15]. In [9] and [16], both extension and vocational education are disregarded. In [6] and [15], extension and research are summed into a single input. The same procedure was followed in [1].

[3] Data on private expenditure on agricultural research by state or region were not available.

[4] In this study the following states were regarded as the South: Virginia, West Virginia, North Carolina, South Carolina, Georgia, Florida, Kentucky, Tennessee, Alabama, Mississippi, Arkansas, and Louisiana. The major cause of this difficulty is the inequality between the racial composition of the school age population some forty years ago (the average age of farm operators in the South ranged between 45 and 55) and the racial composition of the current population of farm operators.

tween the investment and the functions it is expected to perform. Yet the high positive correlations among the inputs (inclusive of the nonmaterial ones) cast doubts on the estimated contribution of a single input. This point is well picked out in this study; e.g., the very high rates of return to extension and vocational education are derived from regression coefficients that are not significant. Hence, a less aggregate analysis (down to individual farm operators) seems to be more appropriate when the aim is the estimation of returns to human capital. Another direction of improvement to be considered regards the simultaneous determination of the quantity of inputs used in production, thus requiring a simultaneous equation analysis (e.g., Mundlak [12]).

The construction of the research capital variable to be employed in the regression analysis as well as the accounting for private research and extension activities are other objectives to be aimed at in forthcoming studies of this type.

"MODERNIZATION EFFECT" UPON EXPORTS OF AGRICULTURAL PRODUCE: SOUTH KOREA: COMMENT

Professor Cho [2] asserts that supply conditions rather than demand deficiency explains much better the post-1945 export lag of agricultural products from less developed countries. This comment accepts this general proposition but takes issue with the example and analysis he used to prove it. In brief, Professor Cho argues that during the Japanese colonial period the Korean land tenure system channeled a large share of the exported rice through landlord hands. Small family farms had little or no rice surplus after paying rent and their marginal propensity to consume rice was high. The postwar land reform redistributed income more equally so that rural rice consumption rose. Cho concludes that this modernization effect influenced supply sufficiently to cause rice exports to disappear.

I seriously doubt that the income redistribution effect of this land reform was strong enough in the early postwar period to cause rural rice consumption to rise. After stating why I believe this to be so, I shall submit an alternative explanation to account for the rice export decline.

Although rents were reduced by governmental decree on October 5, 1945, a maximum rent in money or in kind was limited to one-third of the crop, and all landlords were ordered to file written leases in local land offices, "the rent-reduction ordinance was widely violated, and the requirement about written leases was completely ignored" [4, p. 7]. Landlords continued to receive various special gifts and payments from tenants who preferred not to complain about such practices because of their fear of eviction or retaliation [4, p. 7]. Late in October 1945 roughly 600,000 acres of former Japanese-owned land were brought under the management of the American-created New Korea Company; this land was mapped but not sold to tenants because Korean political leaders could not agree on a plan for distributing privately owned land. In March 1948 the military governor, Major General W. F. Dean, authorized the sale of Japanese land, and the New Korea Company was abolished and replaced by the National Land Administration Agency which sold 700,000 farm plots within several months. A new legislature elected in the same year responded to this action and passed a land reform bill early in 1949. President Syngman Rhee announced the law would be effective on July 1, 1950, but the outbreak of war delayed its implementation until the mid-1950's.

The sudden Japanese departure and collapse of trade and marketing caused severe consumer goods shortages and a near breakdown in trade between towns and countryside, so that the terms of trade turned severely against the peasant and continued in this fashion through the Korean War and into the late 1950's. Cho admits that cities had great difficulty in obtaining rice from villages in South Korea in 1946 [2, p. 95], but he attributes this to the fact that "a relatively high price inelasticity of demand for food has made the income redistribution consequent upon modernization a very forceful factor in determining the export pattern of South Korea" [2, p. 95]. As mentioned above, it is very questionable that an income redistribution effect operated strongly in the 1945–49 period because of the conciliatory manner in which land reform was carried out.

In addition to marketing problems and consumer goods shortages, the south no longer imported millet and sorghum from Manchuria as it did during the colonial period. As the government tried to collect its land tax in kind, the peasantry became even more reluctant to part with their rice. These factors persisted throughout the war, during which a rapidly increasing population and the concentration of more people in the south due to out-migration from the north greatly increased food demand. Finally, the government never made a commitment to develop agriculture, and even now yield and output increase mainly because of crop specialization and increased application of traditional inputs. These developments certainly influenced grain supply conditions enough to eliminate rice exports from South Korea,

but they hardly warrant being termed "modernization effects."

Finally, I would like to compare the Korean agricultural experience with that of Taiwan. Taiwan also exported agricultural products while under Japanese colonial rule and experienced a postwar land reform. But aside from the years 1945–50 agricultural exports increased in the postwar period [3, pp. 252–253]. Only in the late 1950's did the relative share of major agricultural commodities in exports begin to decline below their 1935–37 level [5, p. 27]. Like Korean farms in the colonial period, Taiwan family farms specialized and marketed rice and consumed inferior food, e.g., sweet potato, so that their marginal propensity to consume for rice also was high. In contrast to the Korean 1954–49 land reform, the 1949–52 land reform was effectively carried out and redistributed income considerably, but it did not influence family farm marketed surplus sufficiently to diminish primary product exports. I believe the reason for this was that already by 1951-52 the Nationalist government had successfully restored marketing channels between towns and villages, revived urban industry and commerce, and improved the terms of trade in favor of the peasantry. Thereafter the government invested in agriculture, and farms purchased new farming inputs so that yield and output increased sufficiently to supply enough food for the rapidly increasing population and yet produce a surplus for export.

The factors operating in both the short and long run to cause South Korea's rice exports did not operate with sufficient strength in Taiwan to reduce its primary product exports. The reason for this was that the economy rapidly recovered from the dislocations of the war and the departure of the Japanese; instead of war in 1949–50, the government rehabilitated the economy and adopted an enlightened policy toward agriculture. A recent study of rice marketing in four villages around Suwon city found that while 44 percent of rice output was consumed and the remainder marketed, the marketed surplus was positively correlated with farm size [1, part II]. As yields have only slowly risen after the war and gradual farm fragmentation continues, the marketed surplus of rice naturally has not increased very much. Korean farms simply have not yet experienced a seed-fertilizer revolution like that of Taiwan, so that yield per unit of land still has not risen dramatically. When such a revolution begins to take place in South Korea, there exists the distinct possibility that rice will again be exported in spite of continued farm fragmentation and population growth.

"MODERNIZATION EFFECT" UPON EXPORTS OF AGRICULTURAL PRODUCE: SOUTH KOREA: REPLY

Professor Myers' comment gives me an opportunity to clarify a point that has been easily misunderstood.

Myers accepts my general proposition that "supply conditions rather than demand deficiency explains much better the post-1945 export lag of agricultural products from less developed countries." However, he doubts that income redistribution effect operated strongly in the 1945–49 period in South Korea. To support his assertion, he cites the fact that the land reform bill which passed the Korean Assembly in 1949 was not even implemented until the mid-1950's. The crux of his argument is that income redistribution effect on the order of magnitude I suggested in my article did not operate in the early postwar period because landlords continued to receive very high rents including "various gifts and payments from tenants."

It is true that the land reform bill did not pass until 1949. However, it is wrong to presume that things started to happen only after the bill was actually passed and implemented. On the contrary, even though the period from August 1945 to August 1948 was a period of inaction on the part of the government, it was a most revolutionary period as far as Korean land tenure was concerned, for it was during that time that the private land rights fell apart. It was then that tenants started defaulting on rental payments, and landlords no longer had strong political backing to collect rents. It was also in that period that the de facto government, which preceded the American military government, refused to enforce the private land rights.

Political and social conditions in that revolutionary period were also reflected in the fact that owning tenanted lands ceased to be a prestige factor.

Since most tenants defaulted on rental payments, buying a piece of land to lease was not a profitable investment; and in fact many landlords rushed to sell their lands at whatever price they could get. It is important to note, however, that the tenants who tilled the lands were the only potential buyers, since it was no longer possible to evict tenants. Furthermore, public opinion was overwhelmingly in favor of a sweeping land reform, and it was widely believed the "land-to-the-tillers" reform was just a matter of time. Thus, many events that occurred during that time had a drastic effect on land price, as shown in Table 1.

The mean price of one *chungbo* (2.45 acres) of rice land in the 1945–48 period was less than one-third of the annual production from the land. Most landlords, however, felt relieved if they succeeded in turning over their lands to the tenants at this low price, for they feared that their lands would be expropriated if they did not sell them then.

There had been a very active trading in the land market in the 1945–49 period. Out of about 1,400,000 *chungbo* of tenanted lands outstanding in 1945, 1,026,000 *chungbo* were already turned over to the tenants long before the formal land reform was carried out in the early 1950's. Thus, the formal passage of the land reform bill, or its implementation, was no more than an anticlimax.

What needs to be understood is the fact that during that revolutionary period, most tenants defaulted on rental payments. Of course, there were some exceptions. Rental payments then seldom reached 30 percent of annual production from the land—an amount that was the equivalent of the mean purchase price of the land—whereas in 1954 the new farm owners gave up about 30 percent for both repayment annuity and taxes. Hence, given the high marginal propensity to consume foods among Korean peasants, income redistribution effect upon exports of agricultural produce was particularly strong in the 1945–49 period.

Table 1. Mean price of one *chungbo*[a] of paddy land in Korea

Year	Mean price in *sok*[b] of rice
1935	62
1936	72
1937	77
1938	80
1945 (august)	7
1946 (June)	8
1947 (October)	6

[a] One *chungbo* is 2.45 acres.
[b] One *sok* is the equivalent of 5.119 U.S. bushels.
Source: The Bank of Korea, Department of Economic Research. Also see [1].

This income redistribution effect may explain to a large extent "the collapse of trade between towns and countryside" which Myers so astutely observed. Severe shortages of food in the towns during the period was a stubborn fact that seriously undermines Myers' second contention that "terms of trade turned severely against the peasant." This contention is handicapped further by the fact that terms of trade in the international markets turned in favor of agricultural produce in the period under consideration.

A METHOD FOR ANALYZING THE EFFECT OF TAXES AND FINANCING ON INVESTMENT DECISIONS: COMMENT

The purpose of Rodewald's recent article [2] was to show how the effects of finance charges and taxes can be incorporated into investment decisions. Rodewald has fallen short of his objective in three ways:

(1) He has not considered the tax effects of depreciation charges that can shield substantial income from taxes.

(2) The formulas developed do not take into consideration any value that an asset may have at the end of the decision period (but salvage value is considered in determining after-tax capital gains).

(3) If capital gains or losses are anticipated, their effect is handled incorrectly; if capital losses should occur, the adjustment for taxes proposed by Rodewald is incorrect.

A second area of concern about Rodewald's paper is that the manner in which finance charges are included can lead to inconsistent decisions over time and may result in duplication of costs.

According to Rodewald's model, an investment is desirable when

$$I \leq V_0 = \sum_{t=1}^{k} \frac{E_0(Y_t)(1-T_r)}{(1+r)^t} - \sum_{t=1}^{i} \frac{C_t}{(1+r)^t} + \sum_{t=1}^{i} \frac{I_0}{(1+r)^t} + \frac{\left[I - \sum_{t=1}^{k} D_t - E_0(M_k)\right](1-Tc)}{(1+r)^t}$$

where

I = the investment cost;
V_0 = the value of the investment to the operator at t_0;
$E_0(Y_t)$ = the expectation at t_0 on income to be generated in t;
$E_0(M_k)$ = the expectation at t_0 on the value the market will generate for the asset in year k;
Tr = the tax rate used to compute the income tax liability;
T_c = the tax rate on capital gains;
C_t = the yearly financing charge;
I_c = the investment credit;
D_t = the annual amount of depreciation;
r = the rate used to discount expected income and market value;
t = unit of time;
k = the number of years the asset is expected to be used;
i = the number of years the credit is carried;
j = the number of years the payments are to run.

Depreciation is a noncash expense in the determination of a firm's tax liability. As such it shields a portion of before-tax earnings from tax payments. The tax shield provided by depreciation should be treated as a benefit that will accrue with a decision to invest in depreciable assets. The tax shield from depreciation charges can be incorporated by adding

$$\sum_{t=1}^{k} \frac{D_t}{(1+r)^t}(Tr)$$

to the right hand side of Rodewald's model.[1]

In his initial statement of the decision model, Rodewald included a term for the present value of any future market value that might exist at the end of a project. When he adjusted his model to include tax effects he omitted the term for future market value. This term, $E_0(M_k)/(1+r)^k$, should be part of the decision model.

The last term on the right hand side of Rodewald's model develops the present value after tax of any capital gains that might be expected at the termination of the project life for the investment. Since expectation of market value at the end of a project is considered in determining depreciation, projecting capital gains is a questionable procedure. If Rodewald's procedure is followed the portion of the term within brackets must be negative when there are capital gains. The sign in front of the term must also be negative if the present value after tax of capital gain is to be treated as a benefit. If capital losses were to occur the entire last term becomes meaningless, since capital losses are deducted from ordinary income (assuming there are no offsetting long-term gains, which would be the case when only one investment decision is under consideration).

The second term on the right hand side of Rodewald's model,

$$\sum_{t=1}^{j} \frac{C_t}{(1+r)^t},$$

develops the present value of financing charges. With this factor included, the desirability of an investment is dependent on the method of financing utilized. How an investment should be financed is a separate decision from the desirability of a proposal under study. As Bierman and Smidt suggest, a more serious problem of double counting arises when finance charges are included as part of the investment decision: "The interest factor is taken into consideration by the use of the present value procedures. To include also the cash disbursement for interest would result in double counting" [1, p. 114].

The decision model as adjusted in this comment would read as follows for the situation where straight-line depreciation is used and capital gains are anticipated:[2]

$$I \le V_0 = \sum_{t=1}^{k} \frac{E_0(Y_t)(1-Tr)}{(1+r)^t} - \left[I - \sum_{t=1}^{k} D_t - E_0(M_k)\right](1-Tc) + \frac{E_0(M_k)}{(1+r)^k} + \sum_{t=1}^{k} \frac{D_t}{(1+r)^t}(Tr).$$

GARY T. DEVINO
University of Missouri

[1] This term assumes straight-line depreciation. The term would need adjustment with the use of accelerated depreciation and additional first-year depreciation.

[2] With the 1970 tax revisions, investment credit will no longer be allowed. Rodewald's term for investment credit,

$$\sum_{t=1}^{i} \frac{I_c}{(1+r)^t},$$

has been dropped from the formula.

A METHOD FOR ANALYZING THE EFFECT OF TAXES AND FINANCING ON INVESTMENT DECISIONS: REPLY

I am grateful for the Devino comment, in particular on the capital gains and depreciation aspects of the model I proposed. He is of course correct in saying investment credit is no longer relevant. Other

of his comments need discussion. The basic decision model in question is as follows:

$$I \leq V_0 = \sum_{t=1}^{k} \frac{E_0(Y_t)(1-Tr)}{(1+r)^t} - \sum_{t=1}^{j} \frac{C_t}{(1+r)^t} + \sum_{t=1}^{i} \frac{I_c}{(1+r)^t} + \frac{\left[I - \sum_{t=1}^{k} D_t - E_0(M_k)\right](1-Tc)}{(1+r)^k}$$

where

I = the investment cost,
V_0 = the value of the investment to the operator at t_0,
$E_0(M_k)$ = the expectation at t_0 on the value the market will generate for the asset in year k.
$E_0(Y_t)$ = the expectation at t_0 on income to be generated in t,
Tr = the tax rate used to compute the income tax liability,
Tc = the tax rate on capital gains,
C_t = the yearly financing charges,
Ic = the investment credit,
r = the rate used to discount expected income and market value,
t = unit of time,
k = the number of years the asset is expected to be used,
i = the number of years the credit is carried,
j = the number of years the payments are to run.

Devino made three points explicitly and two implicitly:

(1) The tax effects of depreciation charges were ignored.
(2) The equation failed to take into consideration the end-of-period value.
(3) Capital gains and losses were incorrectly handled.
(4) Investment credit is no longer a relevant item to include.
(5) Including a finance charge in the equation leads to double counting.

For the first of these he suggests a method of handling depreciation tax benefits that should significantly improve the estimates of the tax effect. In response to the changes he proposes for handling points (2) and (3), rather than handle gains with a separate term I would suggest the following:

$$+\frac{E_0(M_k) - \left[E_0(M_k) - \left(I - \sum_{t=1}^{k} D_t\right)\right](Tc)}{(1+r)^k}.$$

The effect is to decrease the expected value by the amount of the capital gains tax. The error he pointed out was that the terms were not in the proper order, which made capital gains negative. In the above formulation the terms appear in the correct order, with Devino's suggested addition, and the sign is correct in all cases. No loss is recognized for tax purposes since in an expectation model of this sort it would seem to make little sense to say on one hand that $E_0(M_k) = \$5,000$ while on the other it is equal to \$17,000 in unrecovered depreciation. Either a loss is expected and is reflected in $E_0(M_k)$, or it is not expected and is so reflected. The objective in both situations would be to aid in determining a value for the minimum annual return required each year of the planning horizon to retire the investment. In either case, k indicated only the planning horizon of the decision maker. Projecting or anticipating a capital value different from the salvage value under these circumstances would seem to be a perfectly legitimate exercise when potential investments are being considered. Losses would show up as negative values for the expected market value and have the required influence on the value for the investment.

The point made by Devino concerning the interest charge is well taken. That is, the present value formulation does include a charge for interest as well as a charge for depreciation. However, if a firm or decision maker must borrow the money so that the interest charge is a cash expenditure each year of the finance period this charge must be included or the value of the investment may be seriously overestimated. These can be included in determining the cash flow or included as a part of the investment cost. To the extent that the economic life of most farm investments rarely coincide with the finance period, the method chosen in the Proceedings paper will allow for a somewhat more exact and easier method of computation. If the finance charge is added to the cost of the investment, these charges should not also be deducted from the cash flow, or double counting will result. If no borrowed money is used, the internal interest charge cannot be added to the investment cost or subtracted from the cash flow without double counting. The method chosen to include the finance charges may not be the best way to incorporate the charges, but I think it is necessary to recognize the consequences of these charges in investment evaluations.

Incorporating the Devino suggestions, the initial formula becomes

$$I \leq V_0 = \sum_{t=1}^{k} \frac{E_0(Y_t)(1-Tr) + D_t(Tr)}{(1+r)^t} - \sum_{t=1}^{j} \frac{C_t}{(1+r)^t} + \frac{E_0(M_k) - \left[E_0(M_k) - \left(I - \sum_{t=1}^{k} D_t\right)\right](Tc)}{(1+r)^k},$$

which will adequately evaluate the investment.

GORDON E. RODEWALD, JR.
Economic Research Service, USDA

RELEVANCE—WHERE DO YOU FIND IT?

In his note of last February, Ernest Grove concluded that the absence of disruption at the AAEA annual meeting in 1969 indicated that "the work of agricultural economists as portrayed and presented at the various sessions last August must be substantially relevant to today's problems and generally useful in dealing with them." Having concluded this "naturally and logically," Grove proceeds to question the "complete relevance of a meeting of agricultural economists in the State of Kentucky at which no mention was made of current problems of tobacco."

While I did not attend the annual meeting, I did thumb through the voluminous proceedings issue in the hope of garnering some morsel of useful information, substantive argumentation, pro or con, concerning current problems of American agriculture. After having done so I came naturally, and I think quite logically, to a conclusion the exact opposite of Grove's. I am not so brazen as to say that all of the papers were irrelevant and/or immaterial. I can't get by with a single exception to my conclusions as Grove did. There were perhaps a half-dozen papers which would, I believe, meet almost any basic test of timeliness and pertinence. Nevertheless, I can think of no instance in recent memory in which it appears that a quotation from Alexander Pope's *Essay on Criticism* could be more appropriate—to wit:

> "Words are like leaves; and where they
> most abound,
> Much fruit of sense beneath is rarely
> found."

Despite a vested interest, considerable training, and long experience in agricultural economics, I find the proceedings issues boring and most Journal papers alternately stuffy, dull, sometimes utterly pointless. If this assessment is accurate, what possible contribution can such writings make to the advancement or preservation of agricultural economics, much less to public enlightenment concerning American agriculture? Journal papers are not written for the general public, but the popularizing of a paper or idea should not be a chore equal to translating Greek or Latin into English.

If I were debating Grove on the subject of relevancy as an explanation for the lack of dramatics at the 1969 AAEA meeting, I would argue the con thusly: Grove's conclusion that the contributions of participants at the last convention must have been "substantially relevant to today's problems and generally useful in dealing with them" is mostly wishful thinking, if not sheer fantasy. An objective appraisal of the work of agricultural economists in the 1960's would, I believe, show the period to have been a rather sterile one. Perhaps it was too much of a contract-research decade—virtually all funded directly or indirectly by myriad Federal agencies. One cannot but wonder if such ballooning research, particularly at the universities, and efforts incident to the execution thereof has not, for the most part, reduced the majority of the profession—high and low—to a conglomerate mass of paper shufflers whose influence in decision making approximates that of office toadies. The lingering uncertainty about this applies only to the universities. At the Federal level, the question is scarcely moot. One by one (few of us really work as a group), our functions have been gradually and unceremoniously turned over, abandoned, or usurped by the political activists—sometimes PR men, lawyers, and/or management experts—whatever they are.

Thus, in stark contrast to Grove's conclusion, I conclude that the obvious indifference and absence of activist participants at the 1969 AAEA annual outing is explained by the fact that the activist element never heard of the organization and little, if anything, of the works of its members.

Over the past decade have we not, for the most part, been writing to and mainly for one another—exchanging drivel in the Journal and at the annual meetings? What real contribution did the profession make during the 60's to the maintenance of a strong and viable agriculture? Perhaps I have overreacted! If so, my timing is as timely as the phrase. Some would probably say, oh, haven't you heard about vertical integration, efficiencies of scale, and all those other advances we helped to promote? Don't you know that the cost of a pound of food in the United States requires only five minutes of the average wage earner's efforts? In contrast, it takes eight, ten, or maybe fifteen minutes in Lower Antarctica. This may sound impressive, but is it? So, in light of the record of the 1960's the question, arises: Why should activist planners—no, just activists—concern themselves with what the AAEA has been doing in recent years or is likely to be doing in the 70's?

For example, is it not true that for the past four or five years a groping, a search—battle, if you like—has been going on to come up with a new farm program, a national policy, for agriculture in the 1970's? I can think of only a half-dozen Journal papers in the past two or three years that relate to this subject, much less attempt to present useful ideas, guidance, or advice. Conceivably, I missed some good ones. The Shechter and Heady article "Response Surface Analysis and Simulation Models in Policy Choices" [2], is an interesting exercise for policy makers to ponder. I fear, however, that the title alone would most likely scare any policy maker rather than attract his attention.

I agree with Grove that relevance is "where it's at" and that we should each "do our own thing" but am in no way persuaded that the mere doing of one's own thing to the best of his or *her* ability is enough, be it advisor or aide-de-camp to the first, or more likely, the thirteenth vice-president in charge of tobacco sweepings, stored peanuts, or hops.

Cool rhetoric is a trademark of professionals and of professional journals, and it should not be otherwise.

Also, it may be well for those over 50 to leave any ideas about hell raising to graduate students and/or younger professionals. However, if the youthful element fails to mount the rostrum to do its thing for the AAEA and/or American agriculture, the older "silent majority" will have to come out of their comfortable (apparently) cocoons and do their thing. To youth, concede youth, nothing more.

IRRELEVANCE IS WHERE YOU FIND IT: COMMENT

Grove [1] has commented on the number of disruptions that occurred at meetings of other professional associations, notably the American Psychological Association, the American Sociological Association, and the American Political Science Association, to name a few. The dissidents at these meetings were mainly graduate students and younger faculty members.

He viewed with a certain amount of satisfaction the fact that our annual meetings in Lexington were completely frictionless while everyone placidly viewed the scenery. Grove rather smugly concluded that the lack of disruption was due to the fact that the work of agricultural economists "must be substantially relevant to today's problems and generally useful in dealing with them." He then took the association to task for not including in its agenda Kentucky's tobacco problem.

I would like to offer four other possible reasons why our meetings were not disrupted. The first is logistic; unlike Rome, all roads do not lead to Lexington.

Secondly, being basically agrarian, the conservative background and upbringing of most of us would never allow such despicable activities. Our fondness for the status quo appreciably restricts any swift forward movement. I hope we never reach the point where we are so complacent that we cannot be critically introspective and make the necessary adjustments.

Thirdly, a weakness of many of the graduate programs in our profession is that an aggressive questioning of the system (be it the profession itself or wider in scope) as it exists is not encouraged, but rather stifled. If a misguided student or younger faculty member does question and does find problems in the system, he may be advised to do so quietly. We seem to be much less tolerant of "boat rockers" in our profession than in other professions. Granted, we turn out highly trained technical people, but are we turning out educated people? We seem to be producing technicians rather than thinkers. "Plug it in and crank it out" may well be the axiom of the day. As a result, our graduate students and younger faculty members may be too apathetic to protest. They may even be too apathetic to be interested.

Fourth, and finally, the relevancy of our work is open for debate. Perhaps our work is so irrelevant, it is not worth demonstrating against. Which is more relevant, the millions of people that have died from emphysema, hardening of the arteries, and heart disease (in 1969 alone 79,637 people in this country died from these ailments [3]) or the fact that half a million farmers (.025 percent of the U. S. population) may have to shift production to a less hazardous crop? Contemplate the grand paradox of government subsidies to tobacco producers at the same time that it bans cigarette commercials from television. Consider the inconsistency when we do not know the extent of malnutrition in the United States [2], but we do know how many pregnant sows are on farms. Consider the myriad of problems that exist in our economy, then tell me about the relevance of the tobacco problem.

Relevance is relative to the times, not to the individual.

DAVID B. NARRIE
Virginia Polytechnic Institute and State University

IRRELEVANCE IS WHERE YOU FIND IT: REPLY

Irony is a less-than-perfect weapon, as Dean Swift must *also* have discovered, for it sometimes seems to have missed its mark entirely.[1] Nevertheless, I welcome the evident misunderstanding by Crockett and Narrie, not only because it persuaded them to make

[1] Mine did not miss entirely. One reader told me, with obvious distaste, "You sure know how to stick needles in people."

some valid observations, but also because it affords me on opportunity to make explicit what I had previously tried to sneak across, so to speak: I felt that the program sessions at Lexington, with few exceptions,[2] were totally irrelevant to anything of importance in the real world.

Although both Crockett and Narrie have thus taken my remarks more seriously than intended and have reacted by castigating our profession, the former has done so from the standpoint of a long-term bureaucrat in agricultural economics, whereas the latter has apparently done so as a recent graduate student. It is remarkable, under these different circumstances, that the two viewpoints are so similar. I must have touched, however backhandedly, on a very sore point!

Both Crockett and Narrie have some good arguments and reach some valid conclusions in their respective areas, but I find myself in more agreement with Crockett than with Narrie. In fact, as a long-term bureaucrat myself, I agree wholeheartedly with almost everything Crockett says. I shall emphasize only one of his points, therefore, and then proceed to my disagreements with Narrie. Crockett laments the displacement of professional economists by management experts of various kinds. This is not new, for the "deprofessionalization of the USDA" has been referred to many times. It needs to be emphasized, nevertheless, because few in our profession are aware of the extent to which the current managerial cult, with its substitution of business management techniques for professional competence, has made inroads on the integrity of agricultural economics research.[3]

This is sometimes referred to as the "managerial revolution," but it is more a fashionable cult than a true revolution. Part of the problem lies in the too enthusiastic acceptance, by government and universities alike, of inappropriate business management techniques and standards. But in part these techniques and standards are themselves defective and therefore inappropriate even in the field of business management.[4] The result has been to make the management of government operations a real disaster area. Crockett seems inclined to exempt the universities from this indictment, but I cannot be so kind. Having been taken over by modern management types, our universities have become or are rapidly becoming "multiveristies," with all the connotations of inhumanity to man—and to students especially.

As to Narrie's four points, they elicit the following replies: 1. All roads do not lead to Lexington. Nevertheless, after the sedative effects of our annual meeting had worn off, the University of Kentucky experienced its full share of disruption. The lesson is clear: A representative democracy such as ours cannot fight a limited but lengthy war because, to soldier and citizen alike, the phrase "limited war" soon becomes a complete contradiction in terms. With no knowledge of what we are fighting for, even Kentucky students can set fire to the ROTC building—as they did after the Kent State affair.

2. We *are* complacent, and we have only just belatedly begun to make the necessary adjustments. Furthermore, I cannot accept the word "despicable" as descriptive of the activities engaged in by student militants. "Unprecedented," "annoying," "misguided," even "stupid"? Yes, possibly. But "despicable"? Emphatically no. I cannot despise courage of any kind, however displayed. And only those who have never tried it are unaware of the courage it takes to confront the establishment with unwelcome dissent.[5]

3. As to the character and quality of present-day graduate education, age must defer to youth in making this judgment[6]—yet I strongly suspect that Narrie has said things here that have long needed to be said. I would, however, question his concession with regard to "highly trained technical people." Most of these are "economagicians" specializing in numerical necromancy, a kind of divination from the entrails of misbegotten and stillborn statistical data.

4. The relevance of our work as agricultural economists is most certainly a legitimate subject for debate. But I disagree with Narrie in his implication that tobacco producers are negligible in number and therefore irrelevant. Relevance may be relative to the times, but individuals, as I said before, can only be relevant in their own areas of competence, usually small. And humanity is not served by the definition of relevance or importance solely in terms of numbers (cf. the parable of the lost sheep).

Let me illustrate this last point in terms of my own feelings and conclusions with regard to the current tobacco-health controversy. Furious objections to the use of tobacco on health grounds extend at least as far back in history as the "King James Counterblast," but somehow these furors have always blown over and the use of tobacco has continued and expanded. The real question, therefore, is whether the current controversy will subside, as all the rest, or whether a new and more lasting factor has been introduced into the tobacco situation.

[2] One notable exception was Bob Schwenger's paper on "New Concepts and Methods in Foreign Trade Negotiation," on pages 1338–49 of what is presumably, and hopefully, our last complete proceedings issue.

[3] A few agricultural economists ought to replace the "Think" signs on their desks with "Grovel" signs.

[4] The American Management Association has a lot to answer for—almost as much as the other AMA.

[5] I say "unwelcome dissent" because mild and innocuous disagreement, which constitutes no real threat to the in-group, may actually be welcomed as it provides a convenient facade of tolerance and "withitness."

[6] I no longer have any contacts at the graduate level. However, my son was in (and out of) a freshman dormitory facing Harvard Yard at the time of the takeover of University Hall, followed by the spectacular early morning bust. So I still have some considerable contact with undergraduate thinking and may be a bit "radicalized" myself as a consequence.

Personally, I think the latter is probably the case. Prior to the last half century, men simply did not live long enough for the ills now being blamed on tobacco to show up in their full force and effect. With the tremendous increase in longevity, however, it is now possible to get statistical samples that are truly "significant." And while absolute and incontrovertible proof, as demanded by the Tobacco Institute, is not yet forthcoming, the odds are now very high that tobacco will remain more or less under a cloud of controversy, if not full censure.

But this has grave implications for the future of tobacco producers and their price support program. I think there is a moral dilemma here, not in the health issue as such, but rather in its probable impact on the economic welfare of tobacco producers. These are effectively *locked in* on tobacco production by the price support program and its accompanying acreage allotment and acreage-poundage programs for cigarette tobaccos, at the same time that cigarette manufacturers are heavily engaged in diversification, taking the word "tobacco" out of their names, and otherwise maneuvering to avoid the consequences of the current health problem. It has even been rumored that cigarette companies are experimenting with marijuana cigarettes on the assumption that marijuana will eventually become legal![7]

Cigarette consumption in the United States started downward in the fall of 1967 and gives every indication of continuing on a downtrend, however slowly. The full impact of this situation has not yet been felt, but it is a dangerous one for producers of cigarette tobaccos, many of whom are still very small by present-day standards. The value of their production rights, now capitalized into the value of their allotment lands, might decline rapidly, to their great economic disadvantage. My conclusion, of course, is that the government should, promptly and generously, offer to buy up the acreage allotments or poundage quotas now outstanding on cigarette-type tobaccos. The values to be used in such a program should be those established in the rental market for production rights in flue-cured tobacco and should probably be the values in 1968, before the decline in consumption was recognized.

This would really cost money, perhaps as much as $3 billion,[8] and would fly directly in the face of the present administration's efforts to maintain a tight budget. For this reason, I would argue further that, if the government cannot afford to buy up these allotments all at once, it should nevertheless be willing to make a down payment, so to speak, by paying growers for any reductions in allotments they are required to make after 1970. This proposal is not likely to get anywhere, but I feel strongly that it should be made. Tobacco has always been the prime example of the capitalization of allotments into land values. At the present time, moreover, it also seems likely to be the first allotment crop in which the economic climate has changed so suddenly and so drastically that these allotment values will be lost, not gradually as has happened in some other crops such as cotton, but quite rapidly, perhaps in only two or three more years.

I trust this brief statement will convince Narrie and others that current problems of tobacco producers should seem highly relevant to concerned agricultural economists. (Are any of us concerned though? That is the question.)

ERNEST W. GROVE
Agricultural Stabilization and Conservation Service, USDA

[7] This has been firmly denied by the companies, but it might conceivably provide a new cash crop for midwestern farmers, who could then adopt another slogan—Permanent Pot Parity!

[8] The sum of $3 billion could be obtained most appropriately by setting aside Federal tax collections on cigagrettes for just 18 months! Total tax collections on all tobacco products—Federal, state, and local—amounted to $4.5 billion in fiscal 1970. The question arises: Who is being subsidized by whom?

IS THERE A BETTER WAY TO CHOOSE THE AAEA PRESIDENT?—COMMENT

There is another possible answer to the title question, one that Harold F. Breimyer apparently did not consider when he gave *his* answer [1]. This would be a sort of open primary, one year in advance. I think it is the best possible answer.

In addition to the form for suggesting names to the nominating committee for future consideration, there would be an actual primary ballot accompanying the current year's ballot. It should list all the names that the committee thinks should be taken seriously for the *coming* year's election, and members would be asked to vote for only two. The two winners would, except under extraordinary circumstances, be the candidates for president-elect in the following year, and their names would be announced whenever the regular election results were to be announced.

A defeated candidate should automatically have his name included in the primary ballot for the ensuing year. I have no fake sympathy for any person who has had the honor of running for AAEA president, even though he may have been defeated. Breimyer says that defeated candidates "are reluctant to expose themselves to rejection once again." All I can say is, "Nuts! Rejection is unavoidable in this life, and there are many more severe and more unfair forms of rejection than defeat in a democratic vote." And besides, under the proposed primary, the two nominees would have a year to bask in their

glory before one of them would have to accept defeat.

I agree with Breimyer that the nomination of more than two candidates is probably not a good idea. But I do not share his apparent faith in the "objectivity" (?!) of a selection committee, however chosen. I think the open primary, one year in advance, is well worth considering. The nominating committee could still function as a sort of umpire.

FAO-U.S. TRAINING CENTER IN CENSUS AND SAMPLE SURVEY PROCEDURES

Since 1967 an international training center has been operated in Washington, D. C., to provide officials, primarily from the less developed areas of the world, with the specialized skills needed to plan and carry out an agricultural census in their countries. FAO initiated the training program as a part of its sponsorship of a World Census of Agriculture under which it was hoped that all 122 members of the United Nations would conduct an agricultural census in or around 1970. The almost universal shortage of people experienced in census operations made it imperative that a comprehensive training program be undertaken. The result was the FAO-U.S. cooperative training project in Washington, which represents a joint effort of FAO, the Department of Commerce, AID, and the Department of Agriculture.[1]

The International Training Program in Washington begins in September; and the first nine months, divided into three periods, are devoted primarily to formal classroom instruction, seminars, and related work projects. Courses are given in statistical principles, sampling techniques, survey procedures, data processing, administrative practices, census methodology, and agricultural economics. Some 75 specialists from the Statistical Reporting Service, the Graduate School of the U.S. Department of Agriculture, and the Census Bureau participate in the training and lecture program.

The second phase consists of a six-week workshop in which detailed data, created for a mythical country called "Agrostan" are utilized for planning and carrying out an agricultural census. In this case study, all aspects of a census become involved, from initial planning through training, field operations, tabulation, and publication. Each participant is aided in relating the "Agrostan" project to his home country situation.

The third phase of the 12-month training involves the participants in an actual census and sample survey project. In the first year this phase was conducted with the cooperation of Washington State University and in the past two years with Pennsylvania State University, with the respective State agricultural statisticians participating. The trainees list the holdings in designated areas, select a sample, interview residents and farmers, edit the questionnaires, tabulate and analyze the results.

Now that many countries have completed their agricultural census, the emphasis in the training program is being shifted from census methodology to sample survey techniques designed to equip participants for the conduct of current sample surveys. This includes special instruction in procedures for making enumerative and objective yield surveys. There is a widespread and continuing need for such sample surveys, built upon the foundation of a census, that will provide dependable information concerning the agricultural economies of developing countries.

So far 144 participants from 59 countries have completed the Training Center Program and a new group started their training last September. Efforts are being made to continue the Training Center indefinitely in Washington for English-speaking participants.

HARRY C. TRELOGAN
Statistical Reporting Service, USDA

[1] A similar training project was conducted for French-speaking participants for nine months in Paris in 1968 but has not been repeated. Also, a three-month regional program has been conducted in South America, India, East Africa, and West Africa.

Reviews

Armstrong, John Borden, *Factory Under the Elms: A History of Harrisville, New Hampshire, 1774–1969*, Cambridge, The MIT Press, 1969, xx + 320 pp. ($12.50)

This history of a small New England mill town is of some interest to economists and others concerned with economic development. The town's future is of likely greater interest. The economist may well speculate that more of a break with the past is in store and that such a break would not necessarily represent degeneration. The author has tried, with some success, to emphasize socioeconomic data and cannot be faulted for his zeal in pursuing these data in detail. The significance of this community, the author concludes, lies in its history of adapting to changing circumstances without destroying its past. The author's preface again points out that the town is somewhat atypical in that it "never became an industrial slum, a ghost town, or the fief of some outside industrial overlord."

Harrisville comes through as a successful company town. It owes its birth to a woolen mill established by the Harris family and its continued survival to decades of paternalistic guidance from the families of mill owners and managers. Housing, churches, schools and social life in the community have all received substantial sponsorship and guidance from these community leaders. Survival of the local mills required close management supervision—and this was given. It required producing a product for which there was a continuing demand—and the mills adapted their product accordingly. It required producing at competitive prices—and the mills did so, both by adopting the latest machinery, equipment, and processes, and by employing immigrants and others who were prepared to work for sufficiently low wages. Continuity of a reliable labor supply was assured by providing housing, both family housing and boarding houses for single employees, and by sponsoring other community facilities, including schools.

Enough is said in the closing pages to reinforce an economist's suspicions that Harrisville's prosperity in the next 30 years will depend on more explicit and more extensive economic and social interrelationships with neighboring communities. In this respect, Harrisville would be typical.

The 1960 population of the town was only 459, down from 748 in 1890. The remaining residents are "older now than the national average and older than was the town's population earlier in its history." The town now sends seventh and eighth graders, as well as all high school students, to school in Keene. And the remaining grades attend school in Chesham because a summer resident of Chesham contributed slightly more than half the cost of a new school. In 1950 this school was "one of the most modern schools in New Hampshire." A superhighway will soon slice through the outskirts of Harrisville. The author estimates that summer residents are now about double the number of permanent residents. Moreover, the summer residents are coming increasingly from New York, New Jersey, and other Middle Atlantic states; and many return for winter sports, while local residents increasingly winter in Florida.

In the light of these happenings, the author's espousal of the continued importance of the woolen mill may seem somewhat exaggerated and perhaps nostalgic:

> Central to both its prospect and its import is the woolen mill, standing symbolically where other New England towns have a common. The survival of the Cheshire Mills is of more than economic significance. Should the mill go under, the town would remain, but it would be at best another New England summer resort. It was the woolen mill of B. Harris and Company that fathered this community, and it is the same manufacturer that gives the town its identity today.

Alan R. Bird
Economic Research Service, USDA

Eicher, Carl K., and Carl Liedholm, eds., ***Growth and Development of the Nigerian Economy***, East Lansing, Michigan State University Press, 1970, vii + 456 pp. ($10.00)

Hill, Polly, ***Studies in Rural Capitalism in West Africa***, Cambridge, Cambridge University Press, 1970, xxviii + 172 pp. ($11.50)

These are welcome additions to the literature on African economies. Part of the contribution is in reprinting widely scattered articles, but both books—and Polly Hill's in particular—also provide new insights to the workings of the agricultural sector in African economies.

The book edited by Eicher and Liedholm takes in the entire Nigerian economy as its term of reference, but most of the growth and development discussed is agriculturally based. Polly Hill's book is specifically addressed to rural phenomena, particularly matters associated with capital accumulation in the rural areas of Nigeria and Ghana, areas that account for some 90 percent of the population of these countries.

Although Nigeria has already been the subject of much of the literatures on African economies, there is good reason for the amount of attention it gets. It is by a good margin the most populous country of tropical Africa. Although like all the countries of tropical Africa its population cannot at present be accurately measured, it appears to have somewhere between 50 and 70 million inhabitants, whereas few of the other forty-odd countries of tropical Africa have populations of over 10 million and many have populations fewer than four million. Nigeria is also of special interest because of the relatively recent discovery there of vast petroleum resources.

The volume edited by Eicher and Liedholm, the product of a 1968 summer workshop at Michigan State University, contains 21 chapters, 16 of which attempt to focus on economic changes in three overlapping periods: during the colonial period (roughly the last decade of the nineteenth century to 1961); between 1950 and 1962; and during the 1960's up to 1967. Another five chapters are devoted to speculation about the economic problems of the 1970's, speculations which, because the book went to press before the outcome of the civil war was known, are not infrequently based on assumptions that have turned to be incorrect.

Of the 21 chapters, 13 are original or revisions and the remaining eight are reprints. Of the original contributions, the chapters by Sara S. Berry on cocoa, J. S. Hogendorn on peanuts, Jerome C. Wells on agricultural planning, Malcom J. Purvis on the oil palm industry, and Scott R. Pearson on petroleum are especially noteworthy. Among reprinted papers are those of A. A. Ayida on supplier contracts, H. M. A. Onitiri on West African economic integration, Wolfgang Stopler on planning, K. D. S. Baldwin on the Mokwa scheme—one of the most dramatic of many African agricultural schemes that have been fiascos—and a paper by Gerald K. Helleiner on the fiscal role of marketing boards.

This is a useful book in bringing items worth reprinting together with related unpublished studies—including the cores of at least four dissertations not yet easily available—but it suffers from a lack of perspective that would have been provided had the editors included materials on precolonial economic history or had they made a more thorough search of the contemporary literature.

Hyla Myint's simple but demonstrably misleading vent-for-surplus model is the point of departure for the opening chapter by Carl Eicher on Nigerian agricultural history and it surfaces again in chapters by Purvis and Hogendorn. Critical to this model is the assumption that new cash crops can be produced with factors that otherwise would be idle, an assumption that appears to have grown more out of Myint's experience in densely populated areas of Asia than his knowledge of Africa.

By emphasizing the impact of access to new overseas markets and ignoring the overland export markets that West African economies have been involved in for as long as we have record, and by postulating idle resources although in fact we have little empirical evidence to support this assumption, as Sara Berry points out in her chapter, Myint's model makes it easy to think of rural African economies as stagnant until colonial powers evoked a surplus and provided a vent for it.

There is mounting evidence that many—perhaps most—of the rural economies of tropical Africa were far from stagnant in the precolonial period. New agricultural enterprises introduced in the colonial era were not the beginning of agricultural change as is often assumed, but merely the latest of several waves of crop introductions and changes in economic organization that date back to at least 1550 [1, ch. 3; 2, ch. 7; 3].

In summary, this book provides a limited, and in part misleading, introduction to Nigerian economic history and a useful sampling of some of the more important literature on government regulatory activity and economic planning in Nigeria. There is a conspicuous neglect of the present behavior of producers, traders, and consumers in rural Nigeria, the domain of Polly Hill's book.

Reporting on cocoa farmers, ocean fishermen, and cattle producers and traders in Ghana and the tobacco trade and inequalities in income and wealth in one area of northern Nigeria, Polly Hill sets out to show that economic activities in African rural economies are far more complex than has usually been thought and involve capital accumulation in ways heretofore largely ignored.

Five of the seven chapters are either reprints or draw heavily on her earlier work, but, especially since hers is the first serious attempt to explore capital accumulation by rural Africans, it is convenient to have this collection of studies under one cover.

The main criticism these essays will receive is that they are long on description and short on analysis. Chapter 5, particularly, on the cattle trade in northern Ghana, is replete with statistics that are of little relevance or, if relevant, only partly analyzed. Less important, but noticeable, are occasional misinterpretations of her data or failure to provide evidence to support critical points, as when discussing Ghanaian exports she states that "exports of palm produce did not fall significantly until cocoa growing had been established 20 years" without providing any evidence whatsoever (p. 24). It is also surprising that having specifically studied cocoa farming in Ghana and being especially interested in capital in rural economies she is content to generalize that the *abusa* sharecropping arrangement involves paying laborers one-third of the crop (p. 71). According to some of my Ghanaian informants, there are a variety of types of *abusa* arrangements, and laborers may receive as much as half of the crop if they provide some of the working capital needed. On the other hand, Polly Hill displays a rare skepticism of conventional wisdom about problems of development and has made impressively detailed studies of the economic activities she has worked on.

This clearly is a major contribution to the literature if for no other reason than that it strikingly changes our conceptual framework. Although it contains only a small sample of case studies from two West African countries, thinking about savings and investment in African rural economies will never again be the same.

Hirshleifer, J., *Investment, Interest and Capital*, Englewood Cliffs, New Jersey, Prentice-Hall, Inc., 1970, x + 320 pp. ($9.95)

Capital theory is a difficult and complex subject. A writer, especially one whose goal is in part synthesis, then, faces an inherently difficult task. Both the complexity of the topic and other reasons have led to certain matters being disputed in a polemical fashion.[1] Part of the controversies arise from the elementary problem that in the process of abstracting from the real world in order to analyze economic phenomena, two analysts may be asking different questions rather than getting different answers. An author whose goal is not to write the last word on the subject (which is not possible in any event), can sidestep much of the controversy by being consistent within whatever abstraction from the real world he adopts. Such is the case with the book here reviewed.

Investment, Interest and Capital is an outstanding textbook, and there is nothing pejorative in a book being called a text. Indeed, the author addresses the book to "the student" in the broadest sense. Hirshleifer has done a real service for any economist who is not a specialist in capital theory. He will also have in his debt all those graduate students who somehow have to summarize and unify a body of knowledge that they probably have been exposed to in a schizophrenic fashion. Aggregate investment is part of macroeconomics; capital accumulation is growth theory; the role of the rate of interest in allocating consumption over time, if taught at all, is part of microeconomics; and the optimal investment decision is part of something called capital budgeting that is taught in business schools. All of this and more, the author brings under one unifying theme.

The book's introductory chapter is a review of price theory in which the general equilibrium values of production, consumption, and price ratios are derived. As in the rest of the book, Hirshleifer uses three ways of expositing this theory: verbal reasoning, mathematical statements and derivations, and numerical examples. The examples are extremely helpful, especially as one progresses through the book. Everything that follows in Part I (two-thirds of the book) is an extension of this first chapter. The first extension is to make the objects of choice for which consumers maximize utility dated units of consumption. For these units the price ratios involve an interest rate as premium for current consumption. Hirshleifer then proceeds to discuss in turn: the optimal investment decision; market equilibrium, i.e., aggregate investment and interest; capital and accumulation; and imperfect funds markets. All of these topics are treated as involving a world of certainty. At the end of Part I the reader will have been exposed to a rigorous but lucid treatment of modern capital theory.

The author, however, goes even further. Part II relaxes the assumptions underlying Part I to allow intertemporal choices under uncertainty. Most readers will have to shift mental gears here. Before getting to the choices, a new set of preference functions must be mastered. In his usual clear fashion Hirshleifer lays out in Chapter 8 the theory of preference under uncertainty based on the Von Neumann and Morgenstern postulates of rational choice. Rather than dated consumption, the choice objects now are contingent consumption claims and, ultimately, dated contingent consumption claims. (His other terminology for the latter is time-state preference.)

These new objects of choice are then used to analyze investment under uncertainty. Now the author

[1] To see that the controversies are far from over, one need only consult Harcourt [1].

can discuss such things as degrees of riskness; incomplete markets, i.e., the inability to exchange all securities; and the type of financing to employ. Unfortunately, the time-state approach has not lent itself well to empirical work; and the author lastly takes up an alternative, the well-known portfolio selection theory in which the objects of choice are the mean and standard deviation of distributions of prospects.

It is to this material in Part II that the author expects, and rightly so, to see the most revision and addition. The relaxation of assumptions has proceeded from allowing time to enter through imperfect markets to uncertain prospects and incomplete markets. Complicated models are not apt to yield simple inferences. The complexities of Part II, however, should not obscure the beauty of Part I.

Hirshleifer's basic abstraction is Fisherian. The goal of economic activity is consumption. Intertemporal choice, then, is among dated consumption claims. A corollary allows consumption decisions to be separated from production decisions. A market rate of interest is then determinate and consistent with both sets of decisions. Whether this abstraction has serious implications for inferences back to the real world is still the subject of dispute. My hunch is that a Knightian quarrel with Hirshleifer's treatment would certainly be less severe than were some of the earlier discussions. Further, the author presents a lucid and straightforward presentation in Chapter 6 of the Knight and Bohm-Bawerk models of capital and accumulation.

An amazing amount of theory is covered in slightly over 300 pages. Some of the conciseness comes cheaply in that much of the material builds on previously discussed material. Some of it will come more dearly for the reader. He must be prepared to read the footnotes, study figures, and do some algebra. (Hirshleifer slips in and solves a simple calculus of variation problem on pages 94 and 95.) With this caveat I recommend the book to any "student" seriously interested in capital and interest. Anyone interested in benefit-cost analysis, capital budgeting, or any valuation-over-time problem can profit by a reading of Chapter 3 on the optimal investment decision.

[1] HARCOURT, G. C., "Some Cambridge Controversies in the Theory of Capital," *J. Econ. Lit.* 7:369–405, June 1969.

Jones, E. L., and S. J. Woolf, eds. *Agrarian Change and Economic Development; The Historical Problems*, London, Methuen (New York, Barnes and Noble, distr.), 1969, xi + 172 pp. (£2; $6.50)

This volume of essays around a common theme results from a seminar held in Reading in the spring of 1968 but reflects only in part its proceedings. There are six independent case studies, with an introduction to set the common frame.

The essays are all competently done, but they are not all equally convincing. R. Zangheri writes with much erudition on Italy's problems of the late Middle Ages and the Renaissance, and for a moment he makes the reader believe that agricultural growth was strong enough so that it might have set off a breakthrough to an industrial society had it not been for the lack of political integration of Italy. How this would have been done before the invention of coking iron and steam power is not touched upon, nor is the core problem of rising industrial productivity in general.

F. M. L. Thompson, in an equally erudite piece on land ownership in England in the eighteenth century, arrives at arguing the developmental merits of landed-property concentration in a few hands on the ground that the landlords' tenant farmers were substantial enough men to buy manufactured goods, including some luxuries. This remarkable calculus eludes the fact that these substantial farmers were relatively few.

E. J. T. Collins, writing on labor supply and demand in European agriculture, 1800–1880, throws some very illuminating light on the mechanisms that made for adoption of early technical advances, such as the transition from sickle to scythe in grain harvesting.

R. P. Dore, in an article reprinted from *Economic Development and Cultural Change*, 1960, condenses some of the best insights on agricultural improvement in Japan, 1870–1914.

C. M. Elliott discourses on agricultural and economic development in Africa, 1880–1914: a very interesting exercise, loaded with relevant information and fresh viewpoints, but essentially (and admittedly) an exercise in rather little agrarian change and still less economic development.

Raymond Carr, discussing the Mexican agrarian reform, 1910–1960, still retains the long repeated and only quite recently refuted judgment of the *ejido* system as a brake on economic development.

The editors' introduction, a full-length essay in itself, tries to tie together some of the disparate strands in the case-study articles. Not as though they thought they had sufficient material for an advanced synthesis. A soberly critical spirit forbids any such extravagances. The editors also conclude on a rather pessimistic note, both as to the relevance of historical parallels from diverse epochs and on the prospects for speedy development of the present low-income countries. It seems to this reviewer that in drawing these conclusions, the writers have made both too much and too little of their evidence. Too much, for it does not sustain quite that much pessimism. Too little, for these immensely thorough

studies contain an impressive treasury of useful data. Agreed, historical analogies are not made of whole cloth, but piecemeal comparisons of partial processes will still give much material for systematic analyses. Agreed, too, that many of the present low-income countries lack much of the preparation that the early industrializers had used generations to achieve; but there are compensations in the speedier transfer of technology and in the higher initial productivity levels that are obtained in this way.

Lewis, Stephen R. (Jr.), *Economic Policy and Industrial Growth in Pakistan*, Cambridge, The MIT Press, 1969, viii + 191 pp. ($8.95)

Stern, Joseph J., and Walter P. Falcon, *Growth and Development in Pakistan*, Cambridge, Harvard University Center for International Affairs, 1970, 94 pp. ($2.75 paper)

To a large extent these two books are complementary reading. The Stern and Falcon book is general in focus and presents a review of factors that have contributed to growth (or nongrowth) in Pakistan since partition and independence in 1947. Those not familiar with the history of Pakistan as well as the nature of the economy likely will find it useful to read this book first, if they are inclined to read both. It is relatively light and lucid reading, presenting only tabular data and offering general explanations or possible explanations of economic change and growth in Pakistan over the last twenty years. Lewis's book, on the other hand, is more analytical and analyzes changes in industrial composition and structure in a fair level of detail.

Neither of these books attempts to draw out any development principles from the Pakistan experience that would be useful for other countries; but then maybe none is appropriate. Stern and Falcon conclude that the Planning Commission has been a most significant factor in Pakistan's growth performance. Their conclusion follows from the fact that planning was initiated under the first five-year plan of 1955 when economic growth was virtually nil and that growth rose to over five percent per annum by the end of the second five-year plan (1960–65).

Lewis is not so generous in his appraisal of planning in Pakistan. Then he has no vested interest in this view. From his detailed analysis he concludes that the following nonpolicy factors were crucial to industrial development: (1) partition, which required Pakistan to transform itself from a supplier of food and raw materials for India in return for manufactured goods into a manufacturing country supplying a significant part of its own needs; (2) generous availability of agricultural raw materials, which could be and were used to manufacture goods for domestic consumption; (3) a relatively large mass market for consumer goods; and (4) relatively simple technologies that were available for producing them. Both books agree that import licenses and tariffs, which permitted manufacturers to obtain large profits that were in a large part ploughed back into industry, gave a tremendous boost to industrial development.

The policy of protection for "infant industries," Lewis concludes from his analysis, has paid off for Pakistan. Growth in "large" manufacturing industries has been near or much above 10 percent from partition through the Second Plan, and relative prices of some manufactured goods have declined. Moreover, some manufactured goods are now moving into export markets. However, domestic prices of many manufactured goods are still 100 percent above C.I.F. prices. Even so, it appears that a significant number of manufacturers today would remain viable under free trade policy.

Stern and Falcon allocate a significant part of their book to agriculture, which is only touched on in the Lewis book. But a relevant conclusion of Lewis is that some of the industrial growth took place at the expense of agriculture through a price policy that resulted in low prices for agricultural products and high prices for manufactured goods. Also, the policy to maintain an overvalued currency curtailed traditional agricultural exports.

But now, according to Stern and Falcon, agricultural development is well on its way, following a change of policy in 1959 to one that subsidizes agricultural inputs and guarantees high prices for grains. Their judgment, however, that Pakistan will shortly move from a food-deficient to a food-surplus position is, according to recent reports on agricultural output growth, likely to be wishful thinking for the present time.

All studies of economic growth seem to leave us with this question: Economic growth for whom and how fast? Pakistan still remains among the low per capita GNP countries of the world, less than $100 per capita despite rapid industrial growth. Agriculture still represents almost 50 percent of GNP. While the industrialists and, more recently, large farmers have become rich through policy programs, much of the general populace remains on the brink of existence. Unemployment has been estimated at 20 percent of the labor force. Underemployment, too, is very high. How to move the very-low-income countries such as Pakistan into developed countries in an acceptable time span is not answered in these books.

An interesting related study of Pakistan by Papanek [1] has this rather startling conclusion: Many of the early entrepreneurs who contributed to Pakistan's industrial development had very little formal education. Moreover, they were just as successful as most of the more highly educated businessmen. Good business sense apparently was gained through their tradesman background. They achieved success in business by contracting with foreign suppliers to set up plants, get them into production, and train personnel

to operate them. This seems to leave the best educational policy for development an open question.

Those interested in the details and some of the mechanics of growth will find that both of these books will help satisfy that interest.

Papi, Ugo, and Charles Nunn, eds., *Economic Problems of Agriculture in Industrial Societies: Proceedings of a Conference Held by the International Economic Association*, London, Macmillan, and New York, St. Martin's Press, 1969, xxix + 671 pp. ($21.00)

We have recently witnessed a proliferation of agricultural economics literature that deals with agriculture by focusing on sectoral interrelationships as opposed to a traditional preoccupation with intrasectoral relationships. Much of this literature has appeared in symposia or conference proceedings. The volume under review, which records the 1966 Rome Conference of the International Economic Association, joins a long and reputable list.[1]

A punctilious review of all 29 papers—let alone the discussion (at times endless) that follows each—might have been feasible but would have been unwise. The alternative is to discuss some of the papers by painting a few strokes of color in an otherwise impressionistic tableau, although by so doing the reviewer may at times appear to be arbitrary in this choice of the papers discussed and captious in his treatment.

E. A. G. Robinson (in an essay which, despite its title, has little to do with "The Desirable Level of Agriculture in the Advanced Industrial Countries") concentrates on some aspects of the familiar "developmental squeeze" of agriculture. He singles out three epochal innovations (to use Kuznets' term) that set in motion the economic pressures for the development of world agriculture. First is the improvement of ocean transportation, including refrigeration, which had already changed the character of competition in the European markets for food products before the end of the century. Second is the application of the internal combustion engine to farming. The advent of the era of mechanical agriculture ". . . released land, the scarce factor, from providing for the supply of horse-power in the most literal sense, to providing food either directly for human consumption or for feeding animals for human consumption" (p. 27). Third is the widespread use of chemical fertilizers and especially the improvements in seeds and pesticides. The influence of these epochal innovations is principally traced out in the case of the United Kingdom—a felicitous illustration of the proposition that agriculture is "at once inevitably subject to almost continuous economic pressure to adjust and also possessed of powerful influence to resist adjustment."

Glenn L. Johnson ("The Modern Family Farm and Its Problems: With Particular Reference to the United States of America") pursues further this proposition. His model emphasizes institutional arrangements that result in individual behavior that is not consistent with system rationality. Within that system Johnson explains both why family farms still exist in the United States and why larger than family farms face difficulties. "It appears that these [family farm] managers make mistakes of over-commitment [of resources in agriculture] *so rapidly* that production is maintained at levels *so high* that prices remain *so low* that larger than family farms have not been able to develop beyond the point where they have to compete in the open market simultaneously for both labor and capital" (p. 246). More generally, Johnson describes the economic pressures ("threats") together with the attempts to resist adjustment ("prerequisites of survival") of the family farm in the United States. The threats are technological advance, the availability of migratory workers to nonfamily-type farms, contract farming, integrated operations, and the problems of entering farming (including intergeneration transfer of ownership). The prerequisites for survival of the family farm include education and research, farmer cooperatives, adequate financing, and public policies designed to preserve the family farm (p. 242).

The discussion on farm size and family farms presented some brighter aspects in other papers. Ulf Renborg ("Tendencies Towards Concentration and Specialization in Agriculture") analyzes the effects of technological innovations on the size of farm and labor productivity and draws some interesting conclusions about the trends for the future. In the beginning of the 1960's small farms (less than 10 hectares) predominated in European agriculture—although a large part of the *arable area* was in farms larger than 10 hectares. The picture was not much different in the United States, where 29 percent of the farms were smaller than 50 acres with 6.5 percent under 10 acres. Furthermore, in the United States 43 percent of all farms had value of sales (in 1954 prices) under $2,500. In terms of employment the great majority of farms in Europe and the United States are large enough to fully employ one to two men. From the point of view of diffusion of technology at the small farm level, the author surmises from the study of Sweden that small farms are well in arrears of present technical potentialities (p. 214). That this is an unstable structure of agriculture is evidenced by a tendency for farms to increase in size, both in acreage and in sales per enterprise. Two conclusions emerge regarding prospects for the future: (1) a movement towards part-time farming as a half-way stop in the transition from farming to

[1] See list of references for some of these.

other occupations; (2) a tendency for the family farm to increase in land size in order to provide employment for one or two employees and to take fuller advantage of the processes of concentration, specialization, and integration.

A more optimistic appraisal of the performance and prospects of the family farm is provided by H. Priebe in "The Modern Family Farm and Its Problems: With Particular Reference to the Federal German Republic." Analysis of a sample of modern family farms in Germany suggests that returns to labor and capital are just as good on family farms as on larger farms. This relative success of family farms is not due to price protection; on the contrary, in Germany the price policy for grain and sugar beets has favored larger farms. Priebe concludes: "The requirements in farm management in a highly developed agriculture, especially, lead to the result that the independent small enterprise of the family farm has proved well suited to development and to the achievement of economic success" (p. 254).

The discussion that followed the slightly divergent views of Renborg and Priebe, as compared to the most pessimistic for the family farm views of Johnson, was lively. Nussbaumer (p. 275) suggested that the disagreement between "the middle European agricultural economists" and the others was due to the sociological importance that the former attach to the maintenance of the conservative family farm.

If the question of small versus large farms is purely a problem of ideological squabbling, it appears that the countries of Eastern Europe still have their share of it. In a stimulating paper, "Problems of the Re-Structuring of Agriculture in the Light of the Polish Experience," J. Tepicht offers a new insight into family farming from the vantage point of the socialist experience. The characteristic of family farming is the subordination of the lot of each individual to the general interest of the family unit. And the function of the peasant economy is to make the greatest possible use of marginal resources, especially of marginal family labor which is satisfied to work for "subnormal returns" as long as this employment means some increases in family income. At the present stage of the economic development in Poland (as well as in LDC's in general) where full employment of the labor force at "normal" wages is not feasible, the role of the family farm becomes crucial. Poland is trying to arrive at a socialist form of agriculture which, rather than being centered on the collective, would realize the advantages of vertical integration for a large number of peasant farms while giving them guarantees against being absorbed by the powerful integrating forces.

Czechoslovakia and Hungary, on the other hand, have gone the opposite direction in this ideological squabble: towards full collectivization. Besides a lackluster agricultural record in both countries, an immediately visible effect of the organization of society around industrial factories in the cities and state-owned factory farms in the countryside is mass exodus from agriculture. Villages have become dormitories for industrial workers. More than one-half of the labor force in agriculture are women and the rest are the aged (Joseph Flek, "Life and Income of Czechoslovak Cooperatives"; László Komló, "The Problems of Vertical Integration in Agriculture: The Hungarian Case").

The difference in emphasis on land tenure arrangements in Poland and in the other Eastern European countries has led to differences in the mechanics of farm integration and agricultural marketing. In Poland the contract system becomes the link between the agricultural units and nationalized industry (M. Pohorille, "Purchasing Contracts and Price Policy as Means of Planning Agricultural Production"). The contract system is simplicity itself, compared with the maze of arrangements that constitute the Russian agricultural marketing system; as an example, agricultural output is sold at "purchase prices" (collective farms), "fixed prices" (state farms), "retail prices minus a trade rebate," or "delivery prices fixed by local bodies on the basis of demand and supply analysis" (K. P. Obolenski, "Agricultural Planning in USSR").

The question of farm size is more than a question of agricultural politics. It is a binary mix of political philosophy and economic performance. Vernon W. Ruttan in an important paper ("Equity and Productivity Issues of Modern Agrarian Reform Legislation") looks at the philosophical and economic rationales of land reform. It appears that the two have led to antithetical policy objectives. Equity was the basic tenet of the political philosophy that led to owner-operated farms in the land reform experience of the United States, Western Europe, and Latin America; and of Japan, Korea, and Taiwan after World War II. Contrariwise, the objective of the land reform in England and in the USSR has been efficiency of production, and it has led to relatively large farm sizes. Perhaps a synthesis of the two objectives is appearing in the more recent land reform programs of Asia—in Malaysia, India, and the Philippines. Evidence has been accumulating that the owner-operated farm is not inefficient (and this reviewer would hazard the guess that it might be more efficient than the large farm within the mode of production of the chemical-biological agriculture). Ruttan submits the hypothesis that there is not a single optimum land tenure system. He concludes that analysis of land tenure policies on agricultural productivity should utilize a behavior model that accounts for the specific economic, technological, and socio-political environment of the country in question. One could not agree more.

Both agricultural protectionism and surpluses were discussed in earnest at the conference. Not surprisingly, it was found that agriculture "deserves" protection: because of the "specific" nature of agriculture, such as the purely competitive markets, the

"inevitability of technical and economic change which increases output per unit of labor," and the "fixity" of resources in agricultural production. As for surpluses, a battery of old and new tricks to deal with them was presented. Among the relatively old: Cochrane's proposal, which receives the major emphasis in Hathaway's paper ("The Search for New International Arragnements to Deal with the Agricultural Problems of Industrialized Countries"). Among the relatively new: the Common Market approach of establishing an "indicative price" (with an actual "intervention price" which is in general 5 to 10 percent lower) which is consolidated by a system of sliding duties, changed daily, the measure of which is equal to the difference between the world market price and the indicative price (Mario Bandini, "Free Trade and Planning in the Common Agricultural Policy," p. 81); deficiency payments (Mouton), which, predictably were rejected by the E. E. C. policy makers since it is one thing to apply the system in a country where agricultural population is 3 to 4 percent of the total—England—but quite another to apply it where the percentage is 30 to 40 of the total. It is not surprising that longing eyes turned towards exports and some kind of international cartelization to dispose of surpluses. D. J. Delivanis ("Problems Arising for the Agriculture of a Developing Country by Virtue of its Association with the European Economic Community") suggested the well-known problems of association in free trade markets of unequal and less developed partners. These countries, having lower productivity and higher costs, have serious difficulties in complying with indicative prices. But, "Should one not welcome the difficulties of farmers in marginal areas, as evidence of progress? Can the Greek economy . . . adapt itself to obtain a high level of economic activity, or will it be forced to restrict the progressive forces because of balance of payments difficulties?" (Robinson, p. 143). This was an anticlimatic admonition, especially coming after a long and sanctimonious discussion about the necessity and benefits of protection and price support programs for the marginal farmer of the United States and the European Economic Community!

The effects of agricultural protection and of surpluses of advanced countries upon trade and exports of less developed countries were too easily dismissed by J. H. Richter ("The Changing Patterns of International Trade Problems of Underdeveloped Areas") on the old—and incorrect—grounds that the main foreign exchange earners of underdeveloped countries are tropical exports. Be this as it may, the prospects for the exports of primary commodities of LDC's are rather disturbing, and therefore bleak is the picture of export-financed economic development. The paper by E. M. Ojala ("Agriculture in the World of 1975: General Picture of Trends") reported on the early projections of the FAO *Indicative World Plan,* and it should be read in conjunction with the more recent work by Louis F. Goreux (e.g., in Thorbecke [4]) and the Wicksell lectures by W. A. Lewis. Especially rewarding on this topic is the paper by V. Martinov ("The Changing Character of International Trade and the Problems of Under-Developed Regions").

Conference proceedings are often constituted of papers of spotty and uneven quality. This is a risk to which international conferences are especially exposed: The problems associated with the dynamics of conference organizing and "conferencing" are compounded with the problems of securing a truly international representation. This conference had its share of "those who also ran." In general, however, the problem of securing quality was rather successfully negotiated by the organizers of the conference. Evidence of this, additional to what has already been reported above, is that the conference also produced some of "those who ran too fast" for a cursory reviewer to be able to do them justice in the space he is allotted. Two examples will suffice: Yair Mundlak ("The Terms of Trade of Agriculture in Context of Economic Growth") and Nicholas Georgescu-Roegen ("Process in Farming Versus Process in Manufacturing: A Problem of Balanced Development"). The latter essay is especially provocative and merits a review of its own. I submit the title, "The Theory of Production and the Analytical Content of Agricultural Economics."

This reviewer thinks that the output and readability of future volumes of IEA conferences could be improved by eliminating the faithful, courtroom stenographic type of recording of each discussant's remarks, which at times are trivial or boring or unintelligible to the reader. An alternative format would be to assign a discussant to each paper whose responsibility would be to present an outline of a discussion paper at the conference and to prepare ex post a full discussion paper which incorporates the main points of the informal discussion that takes place at the meeting—to the extent that they are worth incorporating. It is not easy, but it is a feasible alternative.

Richardson, Harry W., *Elements of Regional Economics,* Baltimore, Penguin Books, 1969, 166 pp. ($1.65 paper)

Those who were in vain looking for a single satisfactory volume on regional economics will receive Richardson's *Regional Economics*[1] with relief. This thick, complete, well-written, rigorous book can be used as the basic text for a graduate course, and parts of it can be used in an advanced undergraduate course. The book consists of three parts, with a balanced allocation of space to each one. Part A covers location theory in four chapters: spatial price theory, transport costs and location, optimal location of the firm, and the general theory of location. Part B is devoted to the economics of the city and contains information not readily available elsewhere to the economics student. In three chapters this part examines urban spatial structure, urban growth, and urban public economy in an interdisciplinary framework. Part C is a thorough presentation of regional macroeconomics; in terms of space it occupies one-half of the book. The author discusses the framework of regional macroeconomics, interregional income theory, regional business cycles, mobility of factors of production, regional growth, policy objectives and efficiency, and the strategy of regional policy.

Reviewers always find issues about which to disagree with authors and I am no exception to this rule. For the reader's sake I shall point out three misleading statements on substantive points.

In arguing for introduction of space into regional macroeconomic models, Richardson states that "we may further assume that the marginal propensity to import of each region is an inverse function of the level of regional income and that income is correlated with a region's size" (p. 272). The second part of this statement is neither obviously nor necessarily correct. What counts is the level of income, not just the size of a region. This however does not negate Richardson's suggestion for explicit introduction of space into regional macroeconomic models, since distance in the form of transport costs and lack of contact between markets affects interregional trade.

On page 409 Richardson argues that pecuniary moving costs may be a source of labor immobility. First, there is some evidence that moving costs are not substantial; second, if moving costs outweigh the expected gains, the existing earnings differences between labor markets do not indicate disequilibrium and thus no question of labor immobility arises. We suggest that it is probably the imperfection in the capital market (for financing migration) that is an impediment to labor mobility.

Again on the question of labor mobility, Richardson (p. 298) states his preference of probabilisitic models over deterministic ones. A probabilisitic model is in essence a gravity model and a deterministic model is one "... in which the rate of migration is determined by objective economic conditions, and individuals are treated as rational economic beings." Richardson's choice of model is a surprising one. In my opinion, gravity models are of limited usefulness as they offer no explanation of the observed human economic behavior. On the contrary, "deterministic" models are consistent with economic theory and when well-specified can do whatever a gravity model can do and more, and better. Parenthetically, one of the gravity models presented is Stouffer's 1940 model of migration and intervening opportunities, and no reference is given to Stouffer's later paper in which he modifies his earlier model [1].

Finally, there is a serious omission in the discussion of the effects of labor movements on the origin and destination of migration (pp. 394–397). Recent work shows that much of the effect depends on the capital-labor ratio of migrants as compared with the same ratio in origin and destination. Capital here includes both kinds, human and nonhuman. No discussion of this aspect of migration is found in the text.

In summary, despite my objections to some of Richardson's statements I find this book excellent and I wholeheartedly recommend it to those seriously interested in adding the space dimension into their stock of economic knowledge.

The second book, *Elements of Regional Economics,* is a short volume based on parts of the first book with a considerably narrower scope, but not a popular version of it. The word "Elements" in the title is not intended to show the depth of the book, but its limited scope. Material not contained in the first book include (1) some empirical evidence on the convergence of regional per capita incomes in Great Britain, (2) a section on the changes of the urban hierarchy in England, and (3) a section on the location-of-industry policy in Britain.

A short chapter is devoted to the presentation of some techniques used in regional planning. The discussions, however, are so brief that they do not allow the reader who is unfamiliar with these techniques to obtain any working knowledge of them or to develop a feeling of appreciation of their usefulness.

Sansom, Robert L., *The Economics of Insurgency in the Mekong Delta of Vietnam,* Cambridge, The M.I.T. Press, 1970, xviii + 283 pp. ($12.50)

Based on interviews in two villages in the Mekong Delta of Vietnam some 30 miles south of Saigon,

Robert L. Sansom has documented a "convincing case... for the economic rationality of the Vietnamese farmer" (p. 209). Sansom's analysis refers to the period in the mid-60's when strong demand forces for agricultural products were being felt. He shows how quickly and rationally the farmers responded to these opportunities, both by adopting production-increasing innovations for rice and by shifting to new crops. Much the most interesting part of his work are the interspersed vignettes of peasant farmer responsiveness. The invention and rapid dispersion of an impeller pump for low-lift irrigation is a classic example of economic response, peasant investment, and intermediate technology. His discussion of how peasants shifted to vegetable production with the development of new markets in Saigon is another example. Equally useful are his discussions of the impact of improved physical security and transportation on cropping patterns as road access was opened up; the spread of fertilizer even for subsistence production; and his conclusion that underemployment in Delta agriculture had previously existed, based on his analysis of small-farmer response to the growing labor demand of the 60's. His compact discussion of the village credit structure emphasizes the importance of unorganized money markets for peasant producers but also the impact of government-sponsored credit. Sansom concludes that the credit market was relatively open and that interest rates, although high, were "probably not a reflection of credit-market control" (p. 106). He finds landlords, moneylenders, and merchants unimportant in 1966 and shows that the predominant sources of credit were relatives, the government, and the *hui*—the revolving credit association of Chinese origin found with various modifications throughout Southeast Asia. (His description of the *hui* is detailed and lucid.) His analysis of the changing rice market illustrates how freeing a market can improve income distribution. Some household accounts would add to his discussion; and although he discusses peasant responsiveness in the production of draft animals, pigs, and chickens, why the curious omission of those flocks of ducks?

For Sansom, the villains of the piece are surely the landlords who were guilty of "widespread economic exploitation and social abuse" (p. 25). One cannot take exception to his concern nor to his demonstration that Viet Minh and later Viet Cong pressures led to a much more equitable land tenure structure, but one could ask for a discussion that probes more deeply into the tenure problem by seeing it in less simplistic terms. It is his black-and-white view of land tenure which is the most important weakness of his analysis, although he considers his treatment of land tenure as a key to his analytical framework (p. 5). He consistently underestimates the social, political, and economic role of the landlord (at least after 1930) and builds a picture of concentration and exploitation which is probably overstated. For example, he interprets the land tenure data for the 1946–67 period to mean that "at least 77 percent" of the farmers were tenants, whereas the data which he himself presents can equally well be summarized to show that 53 percent of the farmers owned at least part of the holdings they cultivated (p. 54). His interest in more equitable land tenure leads him to overstress Viet Cong concern for peasant welfare and understate its desire to eliminate landlords as an opposing political force in the countryside. (His simplistic view of the tenure problem also leads him to underestimate the concern of American officials about land tenure.) As a result, one learns less than he should from Sansom's analysis about the impact of economic environment and market forces on land tenure and their place as a complement to more direct measures leading toward his obviously desirable tenure goal.

The title of the book is misleading: It is a book about the economics of peasant farmers living in conditions of physical insecurity. Sansom does make one important observation about the economics of insurgency, however. He concludes that since markets ignore security conditions and peasants respond to price incentives even in an insecure environment, "in an insurgent war it should be the policy of the counterinsurgency effort to give aid to the inhabitants of the noncontrolled areas" in order to rob the insurgents of economic grievance issues (p. 244).

Announcements

1971 AAEA ANNUAL MEETING

The 1971 annual meeting of the AAEA will be held on August 15–18 at Southern Illinois University, Carbondale, Illinois. Dr. Walter J. Mills, chairman of the Department of Agricultural Economics, is in charge of the local arrangements. Suggestions or requests, including needs for space for committee sessions to be held before or after the meeting should be addressed to Dr. Wills.

The program format for the annual meeting this year will follow the same general outline as that of 1970. Several seminar-type sessions will be organized for the afternoons around basic themes. Subsessions of these seminars will treat more specific topics for discussion purposes. One exception to the program of last year is that contributed papers sessions will be organized as part of the subsession treatment of the main seminar topics. Program organizers for the seminars will be asked to handle the contributed papers in their respective areas.

There will be a general coordinator of the contributed papers topics in order to ensure that the papers are expedited and treated properly. Dr. Charles E. French, chairman of the Department at Purdue University, will be the general coordinator.

Contributed papers will have to compete for time, therefore, with other subsessions of the seminars and with other topics of the annual program. They also will have to compete for time within the specific topical area to which they are designed, as it will be impossible to accept everything from everybody. Like all other subsessions and sectional papers, the contributed papers accepted will have to be abstracted in order to be printed in the Proceedings issue. These papers may, however, be submitted to the Journal in normal fashion as the basis for a complete article.

Information on contributed papers, as well as the other subject matter on the annual program, will be issued separately in a presidential newsletter or another communication to all members.

UNDERGRADUATE DEBATE, PUBLIC SPEAKING, AND ESSAY COMPETITIONS

Competition is open to any undergraduate student interested in agricultural economics. Participants are encouraged to become members of chartered student-section affiliates of the American Agricultural Economics Association, but such membership is not required to enter the various contests. No individual student may enter both the debate and the public speaking competitions in the same year.

Public Speaking Competition

The public speaking may be on any topic in the area of agricultural economics. Each speech will be limited to 10 minutes' duration.

Chartered chapters or individuals must declare their intention of participating in the public speaking competition by writing no later than June 1, 1971, to John Sjo, Chairman, AAEA Student Activities Committee, Department of Agricultural Economics, Kansas State University, Manhattan, Kansas 66502.

Debate Competition

The topic to be debated in 1971 will be announced directly to the departments.

A declaration of intention to participate in the debate competition must be made in writing no later than June 1, 1971, to John Sjo, at the address given above. Names of contestants and/or alternatives and coaches, along with the mailing address of each, should be included. No more than one debate team from one school may participate in the debate contest.

Student Essay Contest

The essay contest does not require attendance at our annual summer meeting. It was developed primarily to provide an opportunity to participate for students who find it impossible to attend the annual meeting and for students whose abilities and interest tend to be in research and/or writing. The development and preparation of a manuscript for purposes of publication is one of the objectives of this contest. Essays may deal with any topic in agricultural economics, agricultural industries, or rural sociology. The 1971 award paper will be published in the 1971 Proceedings issue.

Manuscripts should not exceed 2,500 words in length and should be prepared according to instructions appearing on the inside of the back cover of the *American Journal of Agricultural Economics.* Manuscripts must be submitted in triplicate by July 1, 1971, to Robert Beck, Department of Economics, University of Kentucky, Lexington, Kentucky 40506.

VISITING LECTURER PROGRAM IN STATISTICS

A Visiting Lecturer Program in Statistics is sponsored jointly by the principal statistical organizations in the United States, the American Statistical Association, the Biometric Society, and the Institute of Mathematical Statistics. Leading teachers and research workers in statistics—from universities, industry, and government—have agreed to participate as lecturers. Topics include subjects in experimental and theoretical statistics, probability theory, information theory, and stochastic models in the physical, biological, and social sciences.

The purpose of the program is to provide information to students and college faculty about the nature and scope of modern statistics and to provide advice about careers, graduate study, and college curricula in statistics. Inquiries should be addressed to: Visiting Lecturer Program in Statistics, Department of Statistics, Southern Methodist University, Dallas, Texas 75222.

FELLOWSHIPS IN FOREST RESOURCES

Harvard University announces Fellowships in Forest Resources with stipends up to $15,000 for research and advanced study, open to individuals in public service, academic careers, and private forestry. Inquiries should be addressed to: Committee on the Charles Bullard Fund for Forest Research, Littauer Center 119, Harvard University, Cambridge, Massachusetts 02138.

A NEW JOURNAL

The Southeastern Regional Science Association and the College of Business, Virginia Polytechnic Institute and State University, announce a new journal, *The Review of Regional Studies,* to be devoted to the study of contemporary regional problems—both urban and rural.

The Review is intended as a multidisciplinary forum for the presentation of major analytical and policy issues facing those interested in regional problems. It is hoped that *The Review* will attract as readers and contributors those interested in the solution of these problems. *The Review of Regional Studies* appears three times yearly—spring, fall, and winter. *The Review* is under the joint editorship of: Stanley E. Boyle, Virginia Polytechnic Institute and State University, and Robert T. Miki, Office of the Assistant Secretary of Commerce.

Manuscripts and business correspondence should be sent to: The Editors, *The Review of Regional Studies,* Department of Economics, College of Business, Virginia Polytechnic Institute and State University, Blacksburg, Virginia 24061.

DUES

Dues for 1970 are payable. The dues rates are as follows:

Association	*Regular*	*Junior*
American Agricultural Economics Association	$15.00	$5.00*
Canadian Agricultural Economics Society	$10.00	$5.00*
Western Agricultural Economics Association	$ 3.50	$1.00*
Southern Agricultural Economics Association	$ 3.00	$1.50*
New England Agricultural Economics Council	$ 3.00	$1.00

* For graduate students, three-year maximum, approved by head of department.

Please mail your check, payable to AAEA or American Agricultural Economics Association, to John C. Redman, Secretary-Treasurer, AAEA, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.

News Notes

UNIVERSITY OF CALIFORNIA, BERKELEY

APPOINTMENTS: **Kenneth R. Farrell**, associate director of Giannini Foundation of Agricultural Economics, to develop and coordinate research and extension programs on a statewide basis; **Richard Norgaard**, Ph.D. candidate, Chicago, and **Ronald G. Loren**, Ph.D. candidate, Washington, acting assistant professors.

RESIGNATION: **Norman R. Collins**, to Ford Foundation as program officer in charge of Latin American agricultural programs.

UNIVERSITY OF CALIFORNIA, DAVIS

APPOINTMENT: **Thomas Dickinson**, Ph.D. Michigan State, assistant professor in Environmental Sciences Division.

LEAVE: **Jerry Foytik**, to participate in Education and World Affairs Program to improve teaching and research in Ethiopia, one year.

COLORADO STATE UNIVERSITY

APPOINTMENTS: **Quentin D. Banks**, formerly with Idaho Extension Service, and **R. Burnell Held**, joint appointment in Department of Recreation Resources and Department of Economics, professors; **Forrest E. Walters**, formerly with W. R. Grace and Company, and **Robert A. Young**, formerly with Resources for the Future, Inc., associate professors; **John S. Krebs**, assistant professor of geography.

LEAVES: **Rex D. Rehnberg**, ICA/AID University of Nebraska-MASUA program in Colombia, two years; **Donald D. Rohdy**, consultant to Dean of Agriculture, Virginia Polytechnic Institute, one year; **J. Hugh Winn**, Instituto Technologico Y De Estudios Superiores De Monterrey, Mexico, one year.

RETIREMENT: **C. Richard Creek**, associate professor, after 23 years of service.

CORNELL UNIVERSITY

APPOINTMENT: **Sanford A. Belden**, Ph.D. Purdue; Doyle A. Eiler, Ph.D. Oregon State; **Eddy L. LaDue**, Ph.D. Michigan State; assistant professors.

LEAVE: **Olan D. Forker**, USAID, Turkey, 1970–71.

ECONOMIC RESEARCH SERVICE, USDA

(EDD is Economic Development Division; ESAD is Economic and Statistical Analysis Division; FPED is Farm Production and Economics Division; FRAD is Foreign Regional Analysis Division; MED is Marketing Economics Division; NRED is Natural Resource Economics Division.)

APPOINTMENTS: **Joseph W. Willett**, formerly deputy director, FRAD, director; **Harry E. Walters**, formerly leader of Community Areas Analysis Section, FRAD, deputy director; **Andrew Anton Duymovic**, **John Feaster**, and **Michael P. Steiner**, MED, Washington, D.C.; **Peter Ashton**, NRED, Berkeley, California; **John Baritell**, MED, Pullman, Washington; **Wayne A. Boutwell**, MED, Blacksburg, Virginia; **Herrington J. Bryce**, Brookings Fellow, EDD, one year; **Arthur L. Coffing**, Africa and Middle East Branch, FRAD, Washington, D.C.; **Ivery D. Clifton**, FPED, Washington, D.C.; **Reed E. Friend**, formerly leader of Demand and Competition Section, Europe and Soviet Union Branch, FRAD, assistant branch chief, Far East and Oceanic Branch; **Nancy Hancock** and **Lorin Lovfald**, Far East and Oceanic Branch, FRAD, Washington, D.C.; **John David Hanson**, MED, Ames, Iowa; **Paul L. Holm** and **John R. Schaub**, staff assistants to Administrator; **Philip L. Mackie**, formerly with Foreign Agricultural Service, Europe and Soviet Branch, FRAD; **Ronald L. Mighell**, chief of Production Resources Branch, FPED, Washington, D.C.; **Thomas Twomey**, formerly transportation economist, Far East and Oceanic Branch, FRAD, Washington, D.C.

TRANSFERS: **Walter Armbruster**, MED, from Corvallis, Oregon, to Washington, D.C.; **John Berry**, FPED, from Urbana, Illinois, to Washington, D.C., as chief, Production Resources Branch; **William G. Bursch**, FPED, from Urbana, Illinois, to Lafayette, Indiana; **A. Barry Carr**, FPED, from Stillwater, Oklahoma, to Washington, D.C.; **Donald Chrisler**, FRAD, from Office of the Director to Communist Areas Analysis Section; **Cecil W. Davidson**, FPED, from Washington, D.C., to Urbana, Illinois; **Sam Donald**, EDD, from Washington, D.C., to Alcorn, Mississippi; **Walter Epps**, and **Masao Matsumoto**, from MED to EDD, Washington, D.C.; **Richard Fallert**, MED, from Washington, D.C., to Lafayette, Indiana; **Richard Greenhaigh**, NRED, from Little Rock, Arkansas,

to Columbia, Missouri; **Anthony Grano,** NRED, from Corvallis, Washington, to Office of the Director, Washington, D.C.; **Gerald Horner,** NRED, from Pullman, Washington, to Davis, California; **Edward Jesse,** MED, from Madison, Wisconsin, to Washington, D.C.; **James B. Johnson,** FPED, from Corvallis, Oregon, to East Lansing, Michigan; **Norman Kimball,** NRED, from Madison, Wisconsin, to Berkeley, California; **Mack Leath,** MED, from Stillwater, Oklahoma; **Dudley Mattson,** NRED, from Pullman, Washington, to Washington, D.C.; **Gerald O'Mara,** MED, from Raleigh, North Carolina, to College Park, Maryland; **Melvin D. Skold,** formerly associate professor of economics, Colorado State University, head of the Western Field Research Group, FPED, Fort Collins, Colorado, and professor affiliate, Colorado State University; **Gordon Rodewald,** FPED, from Washington, D.C., to Pullman, Washington; **Otto Thieman,** NRED, from Pullman, Washington, to Little Rock, Arkansas; **Paul Velde,** MED, from Lafayette, Indiana, to Washington, D.C.; **James Vertrees,** MED, from East Lansing, Michigan, to Washington, D.C.; **Virgil L. Whetzel,** NRED, from Land Resources Group to Northeast Resources Group at West Virginia University; **Gaylord Worden,** FPED, from Ames, Iowa, to Washington, D.C.

LEAVES: **Lynn Bickley,** FRAD, to teach in Pakistan; **Robert E. Freeman,** EDD, to teach at Chico State College, Chico, California; **Michael E. Kurtzig,** FRAD, on detail to Foreign Economics Development Service to work on a management training program for high-level Turkish agriculturalists; **Walter Miller,** NRED, to Federal City College, Washington, D.C., one year.

RESIGNATIONS: **Richard A. Benson,** FPED, to accept position in Peoria, Illinois; **Donald A. Carr,** FPED, to accept position at Sacramento State College, Sacramento, California; **Neville Doherty,** EDD, to staff of Health Center (University of Connecticut), Hartford, Connecticut; **Robert R. Fletcher,** NRED, Stillwater, Oklahoma, to Wyoming Agricultural Experiment Station, Laramie; **John M. Himmelberg,** ESAD, to Government Accounting Office; **Richard M. Kennedy,** FRAD, to be USDA coordinator at Virginia State College; **Burl Long,** NRED, University Park, Pennsylvania, to Virginia Polytechnic Institute; **Lyle E. Moe,** FRAD, to Foreign Agricultural Service as assistant agricultural attache in New Delhi; **Roger E. Neitz,** FRAD, to Foreign Agricultural Service as assistant agricultural attache in Bonn; **Robert L. Rizek,** ESAD, to be director, Consumer and Food Economics Division, Agricultural Research Service.

RETIREMENT: **Merton S. Parsons,** FPED, after 33 years of Federal service.

AWARDS: **E. W. S. Calkins,** MED, American Society for Testing and Materials Award of Merit; **Robert V. Enochian,** Western Regional Research Laboratory, Certificate of Merit.

UNIVERSITY OF FLORIDA

APPOINTMENTS: **Carlton G. Davis,** Ph.D. Michigan State, assistant professor with assignment in Guyana under AID-University of Florida contract; **Robert D. Emerson,** Ph.D. Purdue, assistant professor in labor economics; **Gary F. Fairchild,** Ph.D. Texas A&M, assistant professor and research economist with Florida Department of Citrus; **Edna T. Loehman,** Ph.D. Purdue, assistant professor in resource economics.

LEAVE: **Harold B. Clark,** to assist in grain marketing in Indonesia, five months.

AWARDS AND HONORS: **Kenneth R. Tefertiller,** Southern Agricultural Economics Association president, 1971.

UNIVERSITY OF GEORGIA

APPOINTMENT: **Raul E. Yver,** Ph.D. Chicago, temporary assistant professor.

LEAVE: **L. Harlan Davis,** Brazil, as deputy chief, Planning and Development, ARDO, USAID.

IOWA STATE UNIVERSITY

APPOINTMENTS: **Ronald E. Raikes,** assistant professor; **Larry D. Bedford, Brent W. Spaulding,** and **Patricia A. Coffey,** instructors; **Roger A. Norem,** instructor and associate; **Stanley H. Hargrove** and **Uma K. Sirivastova,** research associates.

LEAVE: **Wallace Ogg,** faculty improvement leave, six months.

LOUISIANA STATE UNIVERSITY

APPOINTMENTS: **R. Bruce Johnson,** Ph.D. Missouri, assistant professor; **Robert C. Nelson,** M.S. Louisiana State, instructor.

LEAVE: **Bill Bolton,** South Vietnam, as member of USDA team with USAID to perform an agricultural sector analysis for the Republic of South Vietnam.

AWARDS: **W. H. Alexander,** Associated Milk Producers, Inc. Distinguished Service Award; **E. P. Roy,** L.S.U. Foundation Distinguished Faculty Fellowship Award.

MICHIGAN STATE UNIVERSITY

APPOINTMENTS: **Harold Riley,** USAID mission, Bogota, Colombia, one year; **Lawrence W. Witt,** USAID, Washington, D.C., one year; **Paul Nelson,** U. S. Department of Agriculture, and **Rainer Schickele,** Agricultural Development Council, visiting professors, six months; **Lawrence W. Libby,** Ph.D. Cornell, assistant professor.

RETIREMENT: **Arthur Mauch,** after 32 years of Federal service.

UNIVERSITY OF MINNESOTA

APPOINTMENTS: **Harald R. Jensen**, acting department head, succeeding **Vernon W. Ruttan**, now director of the Economic Development Center; **Malcolm J. Purvis**, Party Chief, Minnesota-Tunisia Project under AID-University of Minnesota contract; **Jerome W. Hammond**, two-year assignment with Minnesota-Tunisia Project under AID-University of Minnesota contract; **Emiel W. Owens**, formerly of Prairie View A&M College, and **Adolf O. Weber**, University of Kiel, Federal Republic of Germany, visiting professors; **John A. Speicher**, Michigan State University, visiting associate professor; **Jonathan D. Anderson**, M.S. North Dakota State; **William E. Griffiths**, Ph.D. Minnesota; and **James E. Hamilton**, research specialists.

LEAVES: **Reynold P. Dahl**, returned from three-year assignment as Party Chief, Minnesota-Tunisia Project; **W. Keith Bryant**, visiting professor and visiting staff economist, Institute of Research on Poverty, University of Wisconsin; **Charles H. Cuykendall**, Cornell University.

RESIGNATION: **Lyndell W. Fitzgerald**, to Food and Agriculture Organization of the United Nations, Rome.

UNIVERSITY OF MISSOURI

APPOINTMENT: **Francis McCamley**, formerly of Kansas State University, assistant professor.

AWARD: **Donald Levi**, Alumni-Faculty Gold Medal Award for teaching, work with students, and alumni-faculty relationships.

NEW MEXICO STATE UNIVERSITY

APPOINTMENTS: **James Gray**, acting head of department, one year; **Stephen W. Fuller**, Ph.D. Kansas State, and **Alan J. Randall**, Ph.D. Oregon State, faculty.

LEAVE: **George R. Dawson**, sabbatical, Cooperative State Research Service, Washington, D.C., one year.

NORTH DAKOTA STATE UNIVERSITY

APPOINTMENTS: **F. Larry Leistritz**, Ph.D. Nebraska, assistant professor in production economics and farm management; **Delmer L. Helgeson**, Ph.D. Nebraska, associate professor in rural and community development.

OHIO STATE UNIVERSITY

APPOINTMENTS: **S. S. Johl**, Punjab Agricultural University, Ludhiana, India, visiting professor until August 30, 1971; **Dick Thomas**, formerly associate professor, associate state leader, Community and Natural Resource Development; **Terry Glover**, Ph.D. Purdue; **Donald Larson**, Ph.D. Michigan State; **Ted Napier**, Ph.D. Ohio State; **Donald Thomas**, Ph.D. Pennsylvania State; assistant professors.

LEAVES: **Kelso Wessel**, returned from two-year assignment in Brazil as member of ESALQ/OSU team; **Richard Meyer**, Sao Paulo, Brazil, two-year assignment with USAID to work on OSU Capital Formation Project.

AWARD: **Wallace Barr**, USDA Superior Service Award.

RETIREMENT: **Ross Milner**, as professor of agricultural economics and rural economics, July 1970.

RESIGNATION: **John S. Bottum**, to be Assistant Administrator, Rural Development, Extension Service, U. S. Department of Agriculture.

OKLAHOMA STATE UNIVERSITY

APPOINTMENT: **Alan R. Tubbs**, Ph.D. Cornell, assistant professor.

RESIGNATION: **Leonard F. Miller**, to Rockefeller Foundation, University of Ibadan, Nigeria.

OREGON STATE UNIVERSITY

APPOINTMENT: **Timothy Hammonds**, Ph.D. Cornell, assistant professor in marketing and price analysis.

LEAVES: **Grant E. Blanch**, sabbatical; **Leon Garoian**, Agricultural Extension Service, University of California, Berkeley, one year; **Albert N. Halter**, Michigan State University, Fall and Winter quarters, 1970–71, working on Nigerian simulation project; **Gary Seevers**, President's Council of Economic Advisors, 1970–71, as senior economist.

AWARD: **Emery Castle**, Distinguished Professor Award, by Oregon State University Alumni Association.

UNIVERSITY OF RHODE ISLAND

APPOINTMENTS: **Bruce W. Mattox**, Ph.D. Oregon State, and **Edmond E. Seay, Jr.**, Ph.D. Iowa, assistant professors in resource economics.

SOUTH DAKOTA STATE UNIVERSITY

APPOINTMENTS: **William F. Payne, Jr.**, Ph.D. Oregon State, and **Jacob E. Wiebe**, Ph.D. Tennessee, staff.

SOUTHERN ILLINOIS UNIVERSITY

APPOINTMENT: **Gordon Honegger**, Ph.D. Purdue, assistant professor.

LEAVE: **Walter J. Wills**, returned from leave at Ege University in Izmir, Turkey, upon death of Herman Haag, to replace him as local chairman for the 1971 AAEA annual meetings at Southern Illinois University and to resume chairmanship of the department.

TEXAS A&M UNIVERSITY

APPOINTMENTS: **John A. Hopkin**, formerly of the University of Illinois, first Stiles Foundation Professor of the College of Agriculture; **Don Mathews**, formerly of Doane's Agri-Service, extension area farm management specialist; **Phi**

Eckert, formerly with USDA, extension economist working with Texas Agricultural Market Research and Development Center of Texas A&M University.

LEAVE: **C. R. Houston,** returned from assignment as Chief of Party for Texas A&M University-USAID Project in Argentina, 1964–1970.

WASHINGTON STATE UNIVERSITY

APPOINTMENTS: **Gerald W. Huettig** and **Richard W. Johns,** associates in research.

WEST VIRGINIA UNIVERSITY

APPOINTMENTS: **Dale K. Colyer,** formerly of the University of Missouri, professor; **Kenneth J. Hock,** assistant professor; **Alfred Barr,** professor of agricultural economics, director of Division of Animal and Veterinary Sciences.

LEAVE: **Ernest J. Nesius,** assistant director in the Office of Domestic Production, USAID, Vietnam.

UNIVERSITY OF WYOMING

APPOINTMENT: **Robert R. Fletcher,** Ph.D. Oklahoma State, assistant professor and extension marketing specialist.

LEAVE: **Rollo L. Ehrich,** returned from two-year assignment as advisor to graduate students and consultant to National Institute of Agricultural Technology, Argentina.

OTHER APPOINTMENTS

Lester L. Arnold, formerly assistant director, Production Credit Service, Farm Credit Administration, vice-president, Federal Intermediate Credit Bank, Louisville, Kentucky.

Richard F. Bieker, Ph.D. Kentucky, assistant professor, University of Delaware.

Ronnie L. Burke, Ph.D. Minnesota, Center for Community Development and Research, Glenville State College, Glenville, West Virginia.

Giorgio Cingolani, Ph.D. California, researcher, Einaudi Foundation, Torino, Italy.

Paul Gessman, Ph.D. Cornell, assistant professor of resource development, University of Nebraska.

Frank M. Goode, Ph.D. Minnesota, assistant professor, University of Tennessee.

R. Clyde Greer, Ph.D. Minnesota, assistant professor, Montana State University.

Charles Edward Harshbarger, formerly of the University of Missouri, Federal Reserve Bank of Kansas City.

John Helmuth, Ph.D. Missouri, Ft. McNair, to teach economics for the military service.

Roger P. Hill, formerly of the University of Georgia, professor of economics at the University of North Carolina.

Gerald W. Huettig, associate in research, Washington State University.

D. Raymond Humberd, Ph.D. Kentucky, assistant agricultural economist, University of Tennessee.

Richard W. Johns, associate in research, Washington State University.

Donald MacLaren, Ph.D. Cornell, faculty, University of Aberdeen, Scotland.

T. David McCullough, Ph.D. Cornell, research, Armour & Co., Chicago.

Richard G. Milk, assistant professor of economics, College of Business Administration, Northeast Louisiana University.

Rodrigo Mujica, Ph.D. California, assistant professor of agricultural economics, statistics, and economics, Catholic University, Santiago, Chile.

Max Myers, South Dakota University, President's Commission on International Trade and Investment Policy.

Glenn Nelson, Bureau of Higher Education, Department of Education, State of Michigan.

Gerald M. Nolte, Ph.D. Minnesota, assistant professor, Wisconsin State University.

Douglass G. Norvell, assistant professor of economics, University of Tampa.

Brian Payne, Ph.D. California, research forester-economist, Northeastern Forest Experiment Station, USDA Forest Service, Amherst, Massachusetts.

Kenneth E. Ogren, formerly agricultural attache, U.S. Delegation to OECD, Paris, staff, President's Commission on International Trade and Investment Policy, Washington, D.C.

M. Ziller Rahman, M.S. Michigan State, Planning and Development Department, Government of Pakistan.

William R. Reilly, Ph.D. Purdue, chairman, Department of Economics and Business Administration, Norwich University, Northfield, Vermont.

Lowell Wood, Ph.D. California, assistant professor of agricultural economics and chairman of the department, Brigham Young University.

Tae-Hee Yoon, formerly senior economist, Dominion Bureau of Statistics, Government of Canada, agricultural economist, International Bank for Reconstruction and Development, Washington, D.C.

OTHER LEAVES

Alfred G. Harms, University of Illinois, Njala University College, Sierra Leone, West Africa, two years.

John W. Wysong, University of Maryland, to study profitability of improvements in grassland and forage handling in Yugoslavia and the United Kingdom, 1970–71.

OTHER AWARDS AND HONORS

Russell H. Brannon, University of Kentucky, AAEA international travel grant to attend IAAE meetings in Minsk, Russia.

W. F. Musgrave, University of New England, Armidale, N.S.W., Australia, editor, Australian Journal of Agricultural Economics, succeeding **J. L. Dillon** of the same institution.

OBITUARIES

Jere R. Boyer, associate extension specialist in food distribution at the University of Hawaii, died in September 1970. Jere was born in Topeka, Kansas, on January 26, 1933. At an early age he moved to Tucson, where he earned his B.S. and M.S. degrees from the University of Arizona. He would have received his Ph.D. degree from the University of Hawaii in 1971.

Jere worked as an extension specialist in New Mexico for three years before going to Hawaii in 1962. He was well known as a consultant in supermarket operations and made numerous trips to Japan, where he instructed Japanese market operators in management techniques.

John Chester Ellickson, who retired in May 1965 from the Farm Production Economics Division of the U. S. Department of Agriculture, Washington, D.C., died in August 1970.

Wells A. Hutchins, a nationally recognized authority on Western water laws, had completed over 62 years of service with the Department of Agriculture at the time of his death in Berkeley, California, in September 1970. Mr. Hutchins began his government career in 1908, with the Department of Agriculture's Bureau of Soils. His service in the Department included the Office of Extension Service, Office of Public Roads and Rural Engineering, Bureau of Public Roads, Bureau of Agricultural Engineering, Soil Conservation Service, and Economic Research Service. The Department gave recognition to his accomplishments with the Superior Service Award and the Outstanding Performance rating.

After reaching retirement age in 1958, following nearly 50 years of Federal service, Mr. Hutchins was reemployed each year so that he could complete his important book on the law of water rights in the western states.

Hutchins' *Selected Problems in the Law of Water Rights in the West* has been a classic in its field since 1942. His work included studies of water law of California, Hawaii, Nevada, New Mexico, Oklahoma, Idaho, Kansas, Montana, Texas, and Utah. He helped many states draw up improved water laws and in the 1940's served as chairman of National Reclamation Association's committee to formulate desirable water law principles for the West. He also lectured on water law and institutions at the University of California at Davis and Berkeley. He was made a life member of the National Reclamation Association and received many other honors for his knowledge and accomplishments in the field of water rights.

AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS

EDITORIAL COMMUNICATIONS

Editorial communications, including manuscripts submitted for publication or inquiries concerning the JOURNAL, should be addressed to Varden Fuller, Department of Agricultural Economics, University of California, Davis, California 95616. (See inside back cover for Guide for Submitting Manuscripts.)

Communications concerning books for review and books submitted for announcement in the JOURNAL should be addressed to Allen B. Paul, Economic Research Service, United States Department of Agriculture, Washington, D.C. 20250.

SUBSCRIPTIONS

· Members of the American Agricultural Economics Association receive the JOURNAL as part of their membership.
· Yearly subscriptions, $25. Price this issue $5.
· Subscriptions, orders for individual copies of the JOURNAL and changes of address of subscribers should be addressed to John C. Redman, Department of Agricultural Economics, University of Kentucky, Lexington, Kentucky 40506.

· The AMERICAN JOURNAL OF AGRICULTURAL ECONOMICS is issued five times a year, in February, May, August, November, and December. Prior to 1968, this JOURNAL was the JOURNAL OF FARM ECONOMICS.
· Published by the American Agricultural Economics Association.
· Printed by the George Banta Company, Inc., Menasha, Wisconsin, U.S.A.
· Second-class postage paid at Lexington, Kentucky, and additional mailing offices.

Agricultural Credit in Latin America: A Critical Review of External Funding Policy*

DALE W ADAMS

During the 1960's aid agencies channelled over one billion dollars to agricultural credit systems in Latin America. This plus local funds boosted the real value of rural credit by 12 percent per year. A number of assumptions underlying past credit policy are critically examined. It is argued that currently credit shortage is not the most pressing issue. Rather, emphasis should be placed on realistic pricing of rural credit and mobilizing rural savings for credit use through interest incentives.

DURING THE 1960's resources for credit made up a large part of externally funded agricultural programs in Latin America. In the ten years 1960 to 1969 the Agency for International Development (AID), the Inter-American Development Bank (IDB), and the World Bank Group (IBRD) provided dollar assistance for agricultural credit worth approximately $915 million in Latin America.[1] IDB made the largest contribution with $439 million, IBRD was next with $255 million, and AID followed with $221 million. Over half of AID's total direct assistance to agriculture in Latin America has gone into credit activities. In addition to this direct assistance, AID has helped channel to agricultural credit institutions several hundred million dollars worth of "counterpart funds" and "local currencies" resulting from program loans and Public Law 480 sales [26]. This has been especially important in Brazil, Colombia, and Chile.

The bulk of the assistance to agricultural credit systems provided by AID and IBRD has gone to Latin America. During the 60's this included all but 10 percent of AID's loans and grants for this purpose and approximately three-quarters of IBRD's loans.

Most countries in Latin America have received substantial credit assistance. Mexico leads with 177 million dollars; Brazil, Colombia, and Argentina follow with 122, 114, and 101 million dollars, respectively. Several of the smaller countries have also received large amounts of external assistance for this purpose: Costa Rica ($30 million), Nicaragua ($45 million), and Paraguay ($37 million). Most AID and IDB loans for agricultural credit have given the borrowing country concessional arrangements: low interest rates, grace periods, and long intervals for repayment.

Despite the emphasis on credit in Latin America, little attention has been focused on the economics of these activities; and very little careful evaluation of these programs has been done. The main intent of the following discussion, therefore, is to evaluate several of the major assumptions that underlie current agricultural credit policy. I tentatively question some of these assumptions in the hope of stimulating further analysis of this topic and suggest several changes which might improve the overall performance of these programs.

Policy Assumptions

Although generalization is somewhat difficult, several common assumptions can be noted in the agricultural credit programs in Latin America:

(1) Credit shortage is one of the major bottlenecks causing low land and labor productivity in traditional agriculture. Not only does a current shortage of production credit exist, but the future transformation of less-developed agriculture will also require major credit infusions.

(2) Concessional lending arrangements for farm credit are justified because: (a) farmers have been exploited by lenders who charge ex-

* Part of the material used in this study was assembled while the author was employed by the Agency for International Development (AID). Additional resources were provided by an AID-funded research project on capital formation and technological change. Charles Blankstein, Kenneth Fedor, Alexis Lachman, J. K. McDermott, Richard Newberg, Stanley Please, Judith Tendler, Philip Warnken, and associates at The Ohio State University, as well as reviewers and editors of the Journal gave helpful suggestions regarding the study.

[1] This information was drawn from AID's "Annual Reports on Capital Assistance and Technical Assistance Projects" (W-253), for June 1969; from various unpublished worksheets of AID's Latin American Bureau; and from various annual reports of the Inter-American Development Bank, International Bank for Reconstruction and Development, and the International Development Association.

DALE W ADAMS *is associate professor of agricultural economics at The Ohio State University.*

orbitant rates of interest; (b) most traditional farmers need special inducement to use highly productive inputs for which credit is necessary; (c) low interest rates are further justified as an income transfer mechanism and/or to offset fiscal or pricing policy that adversely affects farmers.

(3) Little savings capacity exists in rural areas, and marginal propensities to save are low. Almost all funds for credit, therefore, must come from outside the agricultural sector.

Given the emphasis placed on agricultural credit programs, it is disturbing to find very little evidence to confirm these vital policy assumptions. Several of these assertions are questionable, and alternative suppositions should be seriously explored. Unfortunately, with the existing lack of economic research on credit in Latin America, a discussion of this subject must be more suggestive than conclusive.

Agricultural Credit Shortage?

Several different types of information have been used to suggest that a serious shortage of agricultural credit exists in Latin America [30]. The most prominent of these have been: (1) the fact that large amounts of external funds have recently been absorbed by the agricultural credit systems; (2) comparative data showing that countries in Latin America have substantially less agricultural credit than developed countries; (3) the impression that high interest rates in the informal credit market indicate a shortage of credit; (4) the apparent insatiable demand at the farm level for agricultural credit; and (5) the knowledge that technological change in agriculture, which is occurring in parts of Latin America, has a high credit propensity.

Credit absorption

Institutional agricultural credit in the 18 countries analyzed has expanded in real terms rather rapidly, averaging an increase of 12 percent per year over the period 1960 to 1967–68 (see Appendix).[2] Since inflation in some countries has eroded a significant part of the real value of credit funds, this growth is even more remarkable [12]. In 1967–1968, about 4.7 billion dollars worth of agricultural credit was in force in these countries.[3] Parenthetically, this was approximately the amount of farm credit in force in the U. S. Lake States of Michigan, Wisconsin, and Minnesota at the close of 1967 [57].

Even with this sharp increase in availability of credit, institutional funds in almost all countries have not covered total loan requests, and in this sense agricultural credit is clearly still short. Since rather low rates of interest are often charged on these loans, it is unclear whether rates of interest closer to the marginal efficiency of capital would still result in excess demand.

Comparative data

Some evidence on the relative availability of credit in Latin America is shown by comparing the value of institutional agricultural credit with the value of agricultural output (GDP). Ratios for these values are presented in the Appendix (column 4). For comparison purposes, several similar ratios for the United States and Taiwan may be useful. In the United States, for example, total credit for agriculture amounted to over $53 billion at the beginning of 1969 [57]. Since very little institutional credit is available in Latin America for land purchases, it is probably more relevant to remove real estate credit from this figure and use only the amount loaned for rural production and/or consumption—$25.3 billion. Comparing this figure with total gross value of agricultural output in the United States in 1968—$47.6 billion—results in a ratio of .53 [58]. In Taiwan total institutional agricultural credit amounted to about 15.6 billion new Taiwanese dollars in 1969.[4] The gross value of agricultural production in the same year was 39.5 billion new Taiwanese dollars.[5] The ratio of total credit to product was therefore .39.

Agricultural credit in 18 Latin American countries in 1967–1968 was equal to a little over one-third of the aggregate value of total agricultural production in the region (see Appendix). Chile, Costa Rica, Mexico, Nicaragua, and Venezuela all had agricultural credit equal to or greater than half their value of agricultural production. Bolivia, Ecuador, Guatemala, Honduras, Panama, and Uruguay, on

[2] It will be argued later that noninstitutional or informal agricultural credit in Latin America is relatively unimportant.

[3] Care must be used in interpreting absolute values of agricultural credit funds in Latin America. The choice of deflators and exchange rates is very important. Also, in some countries funds used for financing exports of agricultural goods, intermediate market sales of goods, and nonagricultural activities may be classified as agricultural credit. In addition, in several countries loans in default may be a significant part of the total portfolio, e.g., Peru and Venezuela.

[4] Unpublished data from the Farmers' Bank of China.

[5] Unpublished data from the Department of Agriculture and Forestry, Provincial Government of Taiwan.

the other hand, had ratios of credit to output of .15 or less in 1967 or 1968. One might argue that low ratios in a number of these countries are economically justified because subsistence agriculture makes up a large part of the agricultural sector, e.g., Bolivia, Ecuador, Guatemala, Honduras, and possibly Panama. At best, these credit-to-output ratios present a mixed case for agricultural credit shortage in Latin America.

Column 3 in the Appendix presents ratios of agricultural credit to total domestic credit. Bolivia, Brazil, the Dominican Republic, Ecuador, Honduras, and Mexico have substantially increased the share of total credit received by agriculture over the 1960 to 1967–68 period. Colombia, El Salvador, Guatemala, Nicaragua, and Uruguay, on the other hand, have decreased agriculture's credit share. Costa Rica, Mexico, and Nicaragua have very high ratios in this regard; Ecuador, Guatemala, Panama, and Uruguay have surprisingly low ratios, As in the case of the credit-to-output ratios, these agricultural credit-to-total-domestic-credit ratios do not give conclusive evidence on the credit shortage issue. They do indicate, however, that Latin America may not be too badly off with almost one-third of total credit allotted to agriculture.

Interestingly, tests of significance on rank-order and product-moment correlation coefficients relating average annual rates of growth in institutional credit and average annual rates of growth in gross domestic product from agriculture suggest no dependency. The lack of relationship between growth in agricultural credit and agricultural output may be due to time-lag questions or to leakage of credit funds away from agricultural production purposes.

Characteristics of informal credit market

Characteristics of the informal credit system are occasionally cited as supporting the agricultural credit shortage claim.[6] Evidence appears to be rather inconclusive, however, with regard to Latin America. A review of studies on informal credit systems shows that most of the wisdom on this topic stems from experience in Asia [59, 62]. It has been usually held, for example, that private individuals, money lenders, merchants, etc., provide a large part of total rural credit in less-developed areas. In India, for example, studies have shown that less than 20 percent of total rural credit is furnished by the formal credit system [42]. In Thailand only 5 percent of the agricultural credit was reported coming from institutional lenders [53].

Less comprehensive data on several Latin American countries suggest a much smaller role for informal credit. In Ecuador, Stitzlein found only about 10 percent of the total credit used by about 1,000 farmers was supplied by noninstitutional sources [49]. Two-thirds of the farms in his sample had less than 20 hectares, and only about half of the farmers surveyed used credit. Erven found even less noninstitutional credit in southern Brazil [17]. He surveyed 233 commercial crop and hay farms and found that only 3 percent of their total agricultural credit came from noninstitutional sources. In the same general area of Brazil, but among small farm operators, Rask and Rao found only one-third of total farm credit used by 200 small farmers came from noninstitutional sources [41]. Nisbet's study of informal rural credit in Chile showed that noninstitutional credit made up only a little over one-tenth of total credit among the farmers he surveyed [35, p. 170]. Tinnermeier also found that noninstitutional farm credit was not significant among almost 200 farmers in a colonization area of Colombia [54]. Montero likewise found noninstitutional credit to be insignificant for 239 farmers he interviewed in a major agricultural region of Colombia [31]. Although noninstitutional loans made up about one-quarter of the number of loans held by these farmers over a four-year period, they equalled less than 4 percent of total funds borrowed. Anthropological studies by Nash and Tax of Indian communities in Central America showed that institutional credit was almost totally lacking, but they also found that only very modest amounts of noninstitutional credit were used [33, 50]. Likewise, a study in Costa Rica of 320 farms in 1964–1965 showed that only 20 percent of total credit used by these farms was provided by the informal credit system [13].

If these studies are representative, they suggest that the amount of noninstitutional credit in rural areas of Latin America is not very sizable. If there is a large segment of economically justified demand for agricultural credit, the noninstitutional money markets apparently have not exploited the opportunity. One could ask, "Does the lack of a sizable informal credit system indicate a deficiency in effective demand?"

High interest rates in the informal credit

[6] "Informal credit system" is here used to mean credit provided outside the banking system and officially sponsored development or cooperative programs.

market also have been cited as indicating credit shortage. That is, demand pressures face a small pool of loanable funds embodied in a highly inelastic supply schedule. It is therefore concluded that competition for these funds has driven interest rates up and resulted in monopoly profits for owners of loanable funds [59, p. 80].

Again, a review of various studies of interest rates charged in the informal credit markets in rural Latin America strongly suggests that interest rates at best are weak indicators of production credit shortage. It may be that the importance of extremely high rates of interest in the informal credit markets in Latin America has been greatly overstated. For example, Nisbet showed that in Chile a majority of the loans made within the informal credit system which he studied were lent at zero or negative real rates of interest [34]. Stitzlein showed that an average annual nominal rate of interest of less than 20 percent was charged on noninstitutional loans among the farmers he studied in Ecuador, and over 40 percent of the noninstitutional loans in his study carried no interest charge [49].[7]

Another aspect of this question is that relatively high rates of interest may be justified on loans in the informal credit market. The bulk of these loans are small, short-term, unsecured, and mostly for consumption, and lenders' administrative costs are therefore high [4]. Similar loans in developed countries also carry relatively high rates of interest. Moreover, these rates may be justified because of the high opportunity cost of capital in developing countries, lenders' risks, and the substantial rates of inflation that are common in a number of Latin American countries [5, 6]. There is very little evidence available to substantiate extensive monopoly profits in the informal credit market [3, 48].

In conclusion, an analysis of informal credit in Latin America does not present firm proof that a significant shortage of production credit exists in the rural areas. It may well be that these informal credit markets are not large because of the lack of demand for their services and strong institutional competition. It is also apparent that the high-interest-rate problem has been oversold and that current interest rates charged in this market may be rather modest, considering the nature of the services rendered. It may well be that current noninstitutional credit is supplying a market that is largely unrelated to the market for productive agricultural inputs. Thus, marginal costs for credit in this market may be of little or no value in determining the marginal productivity of capital used for agricultural inputs.

Strong demand for institutional credit

Throughout Latin America agricultural credit requests often substantially exceed available funds. From this it has been concluded that a good many economically justified loans are not made because of credit shortage. But, as already suggested, it has also been common to grant credit to farmers at concessional rates of interest. In Colombia, for example, most institutional agricultural credit has been loaned at rates of interest within the range of 7 to 13 percent. Borrowers of capital in the nonagricultural sector, however, pay from 18 to 25 percent for their funds. Hardly a country in Latin America does not have similar arrangements. If the marginal opportunity costs of capital in the country are in the general range of the charges on credit that nonagriculturalists are willing to pay, it is not surprising that agricultural credit is so popular.

Inflation is a further reason for the strong demand for institutional agricultural credit. During the period 1961–1968, six of the Latin American countries experienced average rates of inflation in excess of 10 percent per year—Argentina, Brazil, Chile, Colombia, Peru, and Uruguay. These countries, in turn, extended almost 60 percent of the agricultural credit in Latin America during 1967–1968. During the 1960's a major portion of the institutional agricultural credit in these countries was lent at real rates of interest that were negative; that is, nominal rates of interest were less than monetary depreciation. It is little wonder, then, that borrowers have clamored for negatively priced agricultural credit. Without an adjustment to efficiency prices, it is difficult to determine the economic effectiveness of this strong demand for credit.

On-farm capital formation and new technology requires credit

Again, it has been rather widely held that large doses of credit are necessary to facilitate rapid on-farm capital formation and technological change in agriculture. This view has

[7] Lending by merchants for specific purchases may mask the real charges associated with the lending. Purchase price adjustments may substitute for interest as payment for use of capital. None of the studies available on Latin America explored this in any great detail, however.

been challenged recently by some who argue that development of appropriate new technology must precede expansion of the credit system and that technology may have a low credit propensity [21]. While it is apparent that technological barriers are important in a number of situations, under some circumstances credit can be the leading edge of technological-change policy. Rao has correctly pointed out, for example, that agricultural problems tend to be heterogeneous and that uniform policy prescriptions are often not appropriate [40]. In a study of farms in southern Brazil he found that similar-sized livestock ranches and crop farms had approximately the same amount of capital investment but that credit use was 50 times larger on the units which had switched to crop farming [40, p. 82]. His study suggests that among this particular group of farms, large doses of credit played a leading role in the change from livestock to crop farming. In addition, his data indicate rather serious credit rationing problems. A number of small operators in southern Brazil are blocked from using available technologies such as fertilizer, which are highly productive at the margin, because most institutional credit is absorbed by large operators.

An evaluation of a supervised credit program in Colombia further suggests that a number of small farmers can profitably absorb more credit.[8] This program was begun in 1963 and has extended loans of up to $2,000 per farm in medium-term credit to farmers with modest land holdings [1]. These loans were a substantial increase over the $200 maximum which farmers had previously been able to borrow. Preliminary results of the evaluation indicate that substantial technological change is occurring on many of the participating farms. Borrowers have shifted to more intensive use of their resources; the value of purchased inputs has gone up sharply; much more labor is being used on the farms; and livestock inventories and net worth have grown substantially.

Several recent studies in India also strongly suggest that credit requirements dramatically increase when new technology is used [37, 47]. Additional fertilizer purchases, changes in irrigation systems, and more employed labor associated with use of new seed varieties may require a two- to four-fold increase in cash costs.

While data are inconclusive with regard to widespread agricultural credit shortage in Latin America, these studies suggest that credit bottlenecks may be occurring where the modernization process is most intense and especially among small farmers.

Concessional Interest Rates

Implications for farmers

As already suggested, alleged high interest rates in the informal credit market have been cited as a justification for concessional rates in the formal system. An additional defense for low rates has been that they provide the special inducement necessary to convince farmers to adopt productive inputs. But do farmers need to be bribed to do something that is supposedly profitable? A rather large amount of recent research has shown that farmers profitably allocate the resources at their disposal, including credit.[9] The recent rapid adoption of new cereal varieties in Asia also strongly suggests that farmers in LDC's will adopt very rapidly new technology if it is profitable [9]. A low-interest-rate bribe may simply induce farmers to make expenditures that would not be practical at rates charged for nonagricultural purposes.

Low interest rates for farmers have also been justified as an income transfer mechanism. That is, farmers are given a break on credit because they are presumed poor; or farmers are given concessional interest rates to partially offset national pricing or fiscal policy that adversely affects farm income.

Most of the institutional credit in Latin America is currently lent to relatively large landowners who often have other occupations. Since the income subsidy is tied to credit access, few of the benefits from concessional interest rates are filtering down to the rural poor. It is also an unanswered question as to how much of this fungible credit is leaking out of the agricultural sector through multiple occupational structures. Aside from the political and administrative advantages associated with the "invisible income transfers" through concessional interest rates, the practice has little in its favor. Direct cash payments, development of new technology, subsidizing the price of specific inputs, or adjusting pricing or taxing policies would seem to be a more efficient means of easing farm income problems.

[8] Don Bostwick, James Schwinden, and personnel from the Instituto Colombiano de la Reforma Agraria (INCORA) began this evaluation in 1970. A sample of some 600 borrowers from a total of about 35 thousand was included in the analysis. The credit program is administered by INCORA and partially funded by AID.

[9] No single review article draws together this research. Those wanting additional information on this point might review the discussion stirred by Schultz's book [44].

Implication for credit agencies

Low nominal interest rates combined with high rates of inflation erode the real value of credit portfolios. For example, if the rate of inflation in a country is averaging 25 percent per year and farmers are charged a nominal interest rate of 10 percent, a negative real rate of interest of 15 percent per year is implied. Under these conditions and without principal replacement, the real value of a credit portfolio is reduced to half its original value in a little over four years.[10] As suggested earlier, the high rates of inflation in Argentina, Brazil, Chile, Colombia, Peru, and Uruguay have resulted in negative real rates of interest having been charged on a large part of institutional agricultural credit during the 1960's. In Brazil a subsidy of $100 to $200 million per year has moved through institutional lending agencies to agricultural credit borrowers via these negative interest rates. Given this, it is even more remarkable that most high-inflation countries, with the exception of Uruguay, have been able to increase substantially the real value of their credit portfolios. Because of the capital washout, a much larger amount of capital has been transferred into agricultural credit systems than is indicated in the Appendix by the difference between dollar values of credit in 1960 and 1967–1968.

This capital erosion has obvious adverse effects on lending agencies. It tends to decrease the real value of the loan portfolio and forces the agency to look to external assistance for funds to increase its real size of portfolio. Under conditions of positive real rates of interest, lending agencies can build their portfolios by generating some internal profits. Because of low-interest-rate policy throughout most of Latin America, internal profits have been negligible. In addition, abstracting from the capital erosion problem, interest rates are often too low to pay out-of-pocket expenses. This is especially true where intensive supervision is tied to credit and overhead costs may run as high as 10 to 25 percent of the loan portfolio per year [1, 2, 11, 15, 19, 24, 29, 32, 36, 43, 55, 61]. Since overhead costs cannot be covered under these conditions, administrators are not "under-the-gun" to watch closely other administrative costs. Flabby administration can result.

It could also be argued that by holding the interest rates down governments have kept the private banking system and the informal credit market from providing substantial amounts of credit to agriculture. Governments thus are forced to try to legislate, usually unsuccessfully, the granting of agricultural credit by private banks [52].

In summary, there appears to be no strong set of reasons for granting concessional rates of interest to agriculture in Latin America.

Rural Savings Capacity

Little attention has been paid in the literature to capital formation and savings capacity in agriculture. Nurkse, Lewis, Ranis and Fei et al. effectively directed developers' attention away from this issue by stressing the use of "surplus" rural labor to form capital in urban settings. Because rural people were often poor, it was widely held that savings capacity in agriculture was very low and that little capital formation was taking place. It has also been assumed that these rural residents have low marginal propensities to save [28, p. 289]. Several important conclusions followed from these assumptions: (1) Little investment takes place on farms in less developed countries; (2) most investment that does take place must be financed by credit provided from sources outside of agriculture; (3) mobilization of capital from the agricultural sector must be largely done on an involuntary basis; and (4) since little savings capacity exists, institutions and incentives to save are not necessary in rural areas. Under these assumptions it is not surprising that international lending agencies have not encouraged countries to mobilize rural savings by offering favorable rates of interest as well as institutional forms.

A review of data on time deposits in savings institutions in Latin America shows that voluntary savings are relatively insignificant when compared to figures on domestic credit claims on private sector [22, 27]. This is especially true in Brazil with a ratio of savings to credit of only .13 in 1968. Bolivia, Chile, Colombia, Costa Rica, Ecuador, Nicaragua, Panama, Paraguay, and Uruguay had ratios of less than .40. The 18-country totals for Latin America show a ratio of only .42 in 1967 or 1968. Only Mexico has roughly as much voluntary institutional savings as domestic credit, a pattern that is general in developed countries.

Monetary depreciation, coupled with fixed low interest rates on savings, has provided little incentive for people to institutionalize savings.

[10] This can be calculated by using $i=1-1/1-R$, and $V=1/(1+i)^n$, where R=negative interest rate, i=a conversion factor, n=number of years, and V=half value in year n.

In Colombia, for example, the Agricultural Bank, which handles about one-half of the country's savings, pays only a 4 percent rate of interest; i.e., a rather healthy negative real rate of interest during the 1960's.

Unfortunately, very little information is available on how responsive rural people in Latin America might be to increases in the rates of interest paid on savings. Recent experience in Korea, however, suggests that the supply of savings may be rather elastic with respect to interest rates. In the last part of 1965 Korea approximately doubled the rate of interest that could be paid on time deposits [8]. Since this interest rate reform, the amount of time and savings deposits has doubled each year and an eightfold increase in number of savings accounts has been experienced. Unfortunately, there is no information available on how much of this dramatic increase in savings came from the rural area. There is little reason to think, however, that rural people did not participate in this in a major way.

In the early 1950's Taiwan was also quite successful in mobilizing voluntary savings by raising interest rates [10, 23]. Less well-documented cases of recent substantial increases in institutional savings resulting from interest incentives have also occurred in Indonesia and Turkey.

It may be that if rural people in Latin America had adequate economic incentives and access to a savings institution, substantial amounts of local capital could be mobilized to significantly complement external funds for credit, especially where income is increasing. Currently, rural people must hold savings in land investments or in livestock. The growth in credit unions during the past five years in Latin America shows that some additional capital can be mobilized if institutional forms are simply available [20]. Between 1963 and 1968, funds in credit unions in Latin America increased from less than 8 million dollars worth to about 57 million dollars [14, 25]. Approximately 30 to 40 percent of this has been raised in rural areas.

Present policy in Latin America results in large subsidies to credit users and yet almost completely discourages institutional savings. Does a significant amount of potential savings exist in rural areas of Latin America? Evidence from studies in Bolivia, Brazil, and Colombia suggests that rural savings capacity does exist [16, 18, 46, 60]. Could mobilization of these savings, especially in areas where rapid technological change is occurring—southern Brazil, Central Venezuela, and the Cauca Valley of Colombia, for example—provide a substantial portion of the agricultural credit needs? The possibilities look favorable enough to warrant focusing some policy attention on this area.

Conclusion

During the 1960's agricultural credit in Latin America was sharply increased. While still larger amounts will be needed during the 1970's and 1980's to facilitate further development, I would argue that policy priority ought now to be shifted away from simply increasing amounts. Emphasis should rather be placed on creating firm financial and economic foundations for rural credit systems.

In brief, I would suggest the following three issues for emphasis:

(1) Where interest rates on agricultural credit do not reflect opportunity costs of capital, high priority should be given to raising rates.[11] Market forces should have more sway in the allocation of these funds. Higher rates would likely enable small farmers to get and use more credit as large operators back away from credit with higher costs. Increased rates would also allow credit institutions to protect the real value of their loan portfolios and make them less dependent on external funding. More realistic interest rates would also encourage the growth in nongovernmental credit. Private banks, merchants, and other informal sources of credit would find it more profitable to participate in this activity.

(2) Far too little of the agricultural loan portfolio in Latin America is currently supplied by rural savings. An important increase in savings capacity is resulting from the expansion in rural income streams in a number of areas in Latin America. I feel that higher interest rates on institutional savings could help mobilize a significant part of this savings potential and that these voluntary savings could provide a major portion of future rural credit needs.

(3) More realistic prices on agricultural credit would bring into sharper focus the major constraints that are slowing agricultural development. Credit policies in a number of countries are currently obscuring these constraints. It is difficult, for example, to tell if input or product prices are seriously out of line. The economics of new technology, land tenure restraints, the

[11] Value linkage or principal readjustment should be explored in cases of very high rates of inflation [36].

importance of marketing and transportation costs, and the role of educational inputs are masked in many cases by current credit policy.

In a number of Latin American countries higher prices on agrucultural credit and rural savings will entail major changes in farm pricing policy, fiscal programs, and monetary policy. In order to encourage general movement in this direction, aid agencies will need to face Latin American countries with a united front. One agency's loan program that requires higher interest rates to be paid by farmers will not float in a sea of heavily subsidized credit.[13]

In order to convince countries to alter current policies, aid agencies must be well briefed on what their credit programs are achieving. Unfortunately, aside from a couple of cases of evaluation by AID and a few brief visits by IDB and IBRD officials, the economic results of the aid agencies' "billion dollar agricultural credit program" during the 1960's has been undisturbed by systematic research.

Appendix. Agricultural credit, rates of change, ratios to total credit, and gross domestic product from agriculture for 18 Latin American countries, 1960 to 1968

Country and year	Institutional agricultural credit year-end balances[a]

[13] The difficulties recently experienced by the World Bank in Brazil on a livestock loan which was value-linked is a case in point.

* Net domestic product figures are used here rather thai gross domestic product.

** Includes some data estimated by the author.

*** Data is for new loans made during the year, rathe than year-end balances.

[a] Figures on agricultural credit represent institutiona lending and were taken mostly from annual or monthl reports of each country's central bank. In several cases annual reports of individual banks were used, and in one o two cases, unpublished Agency for International Develop ment reports were used.

[b] Local currency values in each case, except that som data for Mexico (see footnote[d]) and Chile (see footnote[e] were adjusted by the yearly consumer price index figures with base in 1963, published by the International Monetar Fund [22]. The 1963 exchange rate of local currency fo dollars was then used to convert to an "adjusted dolla value." The figures in the table, with the exceptions noted therefore show the 1963 purchasing power of local currenc in credit funds expressed in dollars.

[c] Agricultural credit (col. 1) divided by the correspond ing domestic-credit-claims-on-private-sector figure, take from International Monetary Fund [22]. The adjustment explained in footnote [b] were also made in the domesti credit claims on private sector figures.

(*Appendix footnotes con't. on next page*)

[d] Agricultural credit (col. 1) divided by the corresponding gross domestic product from agriculture for 1967, taken from United Nations [56]. For Brazil, 1968 GDP figures were used; for Bolivia, only 1966 figures were available. The adjustments explained in footnote [b] were also made in the gross domestic product from agriculture figures, except for Mexico. Mexican data were expressed in 1950 market prices and converted to dollars using the 1950 exchange rate of 11.57 pesos per dollar.

[e] Local currency values in Chile were adjusted by a yearly price index with base in 1965. The 1965 exchange rate of escudos was then used to convert each year to an adjusted dollar value. The figures for Chile therefore show 1965 purchasing power of escudos expressed in dollars.

A Welfare Analysis of the Voluntary Corn Diversion Program, 1961 to 1966*

LEROY J. HUSHAK

The welfare effects of the corn diversion program are analyzed. A three-sector (corn, other crops, and the rest of the economy) supply-demand model is developed which incorporates substitution in production and consumption between corn and other crops. Using observed data as the restricted market equilibrium and parameters derived from previous research, free market equilibrium is estimated. The net welfare costs and income transfers are computed from the two equilibrium points. In general, the net welfare costs are small and the income transfers are substantial. However, the model is quite sensitive to the parameter values.

NUMEROUS STUDIES have been made of the impacts of United States agricultural policy, but two areas of weakness stand out. First, relatively few studies have been made of policies regulating the major crops for which significant substitution exists in both production and consumption, compared with analysis of the impacts of policy in the aggregate or on crops whose production is limited geographically and for which substitution is not significant. This study singles out corn and develops a welfare analysis of the voluntary corn diversion program during the 1961 to 1966 period. Second, an analytical framework is needed which allows the consideration of substitution among crops and the simultaneous analysis of several individual crop policies. A step is taken toward filling this need by expanding Wallace's input control model [14, p. 585] from two to three sectors, i.e., from crops and the rest of the economy to corn, other crops, and the rest of the economy. The model takes account of the effect of the corn program on both the corn market and the other crop market, in which other crops are assumed to be free of regulation and the rest of the economy is assumed to be unchanged.[1]

The voluntary corn diversion program began in 1961 under the feed grain program [11]. Background data on corn for grain during this period are presented in Table 1. The program imposes two restrictions on the market which are of concern. The first restriction is the support price, the price fixed by the government at which it buys or sells corn.[2] The government buys or sells enough corn to maintain the price.

The second restriction is on land in the form of direct payments to producers for taking land out of corn production. To receive direct payments, a producer must take a minimum of 20 percent of his average corn acreage before the program (corn base) out of corn production. He may retire and receive payments for 40 percent or more of his corn base, depending on expected production for the year. The land must be kept under a cover crop or summer fallow, and no crop may be harvested from it.[3]

The payments have taken three forms. In 1961 and 1962 payments were equal to about 50 percent of average yield[4] per acre times the support price for each acre removed from production. From 1963 to 1965 a subsidy of 15 to 20 cents per bushel on actual production was paid, in addition to a direct land payment of 20 percent of average yield per acre times the support price per acre removed. Beginning

* This research is part of the author's Ph.D. dissertation completed at the University of Chicago. The author is grateful to the Ohio Agricultural Research and Development Center for the time required to complete this paper and to H. Williams, A. Schwartz, and the Journal reviewers for valuable comments on earlier drafts.

[1] The expansion of the Wallace model to an unlimited number of sectors is conceptually straightforward. The model of this paper is limited because the required parameter estimates expand rapidly with additional sectors, and it is not clear that the effects of a particular policy can be isolated in an expanded model. This lack of consideration of restrictive policies on other crops and the additional assumptions below make the model somewhat naive; but it is not clear that a more detailed model will result in better estimates, given our knowledge about the parameters of this or a more detailed model.

[2] While the price at which the government sells corn is greater than the price at which it buys corn at any point in time, no attempt is made to take this difference into account. To the extent that this difference is based on storage and transportation costs, which are excluded because the model is analyzed at the point of production, the omission will not cause any significant bias.

[3] While the Secretary of Agriculture has the option of allowing certain crops to be grown on retired land, the option was not used during the 1961–1966 period.

[4] Average yield is an average of yields from 1959 to the last year of production.

LEROY J. HUSHAK *is assistant professor of agricultural economics at The Ohio State University.*

Table 1. Data on corn for grain, United States, 1961–1966

	Support price	Market price	Output	Yield	Harvested acres	Government Stocks October 1
	dollars per	*bushel*	*million bushels*	*bushel per acre*	*million*	*million bushels*
1960		1.00				
1961	1.20	1.10	3,626	62.0	58.4	1,371
1962	1.20	1.12	3,637	64.2	56.6	867
1963	1.07[a]	1.11	4,092	67.6	60.5	803
1964	1.10[a]	1.17	3,584	62.6	57.3	828
1965	1.05[a]	1.16	4,084	73.8	55.3	540
1966	1.00[a]	1.24	4,103	72.1	56.9	249
1967						139
Average	1.10	1.11[b]	3,854	67.0	57.5	

[a] Does not include direct subsidy payments of 18 cents per bushel in 1963, 15 cents in 1964, 20 cents in 1965, and 30 cents in 1966.
[b] Average for 1960 to 1965.
Source: [10, year 1967].

in 1966 a subsidy of 30 cents per bushel was paid, based on average yield projected to the current year times the smaller of acreage planted or 50 percent of the corn base, with no direct payment for the first 20 percent of land removed. If additional land was retired, it was paid for directly under all versions of the program.

Direct payments for land and subsidy payments provide an alternative use or rent for land which producers will take if the rent to the land retired is greater than the rent would be if they did not participate in the program.[5] The government develops an estimate of the amount of land needed to produce the desired quantity of corn each year and sets a payment structure that will induce producers to divert enough land to reach that amount, fixing the quantity of land used for corn.

With the above as background, the next section develops and illustrates the free and restricted market models, after which the welfare analysis is developed. A third section provides estimates of free market equilibrium and the results of the welfare analysis. Finally, estimates are developed of the costs of administering the program and of storing stocks of corn, costs not included in the model. The analysis is limited to short-run (1–2 year) to medium-run (3–5 year) adjustment periods.

[5] The question of who receives this rent is discussed more fully later. A second effect of these payments is that producers, given participation, have a long-run incentive to increase yield to increase payments. The model assumes a yield equating price and marginal cost. Direct payments based on yield may cause the marginal revenue of additional yield to exceed the price of corn because of higher future payments, if the program is expected to continue for several years. This second effect is not considered.

Supply-Demand Model

The objective of this section is to specify the functional relationships of the free and restricted markets from which the welfare effects of the corn program can be computed. This involves two supply-demand models, a free and a restricted model, which can be directly compared. Each model explicitly consists of two sectors—corn and all other agricultural crops—and two factors of production—a fixed factor, land,[6] and a variable factor comprised of all other factors of production. The rest of the economy is not considered explicitly because it is assumed unchanged. Further limiting assumptions are: profit-maximizing firms, competition in the product and factor markets, the existence of a restricted market equilibrium in these markets, a constant level of technology, and unchanged population. The models are static; time enters only in the sense of the period required to move from the restricted to the free market equilibrium. The income effect of the program is not included.

The free market model (sector 1 is corn and sector 2 is other crops) is[7]

$$(1) \qquad X_1^d = B_1 P_1^{\eta_1} P_2^{\eta_{12}}$$

$$(2) \qquad X_1^s = C_1 P_1^{\epsilon_1} P_2^{\epsilon_{12}}$$

$$(3) \qquad X_1^s = X_1^d$$

$$(4) \qquad X_2^d = B_2 P_2^{\eta_2} P_1^{\eta_{21}}$$

$$(5) \qquad X_2^s = C_2 P_2^{\epsilon_2} P_1^{\epsilon_{21}}$$

$$(6) \qquad X_2^s = X_2^d$$

where

X_i^d = quantity consumed ($i = 1,2$, 1 = corn 2 = other crops)
X_i^s = quantity produced
P_i = price
η_i = own-price elasticity of demand
η_{ij} = cross-elasticity of demand for X_i with respect to P_j ($i \neq j, i,j, = 1,2$)
ϵ_i = own-price elasticity of supply
ϵ_{ij} = cross-elasticity of supply of X_i^s with respect to P_j ($i \neq j, i,j, = 1,2$)
B_i, C_i = constant terms.

Equations (1) and (4) are demand functions

[6] See footnote 5.

[7] The functional form of the model is constant elasticity (linear in the logarithms). On the supply side this form is implied by the generally superior performance of the Cobb-Douglas function over additive functions in the estimation of production functions. For simplicity the demand functions are assumed to have the same functional form.

for corn and other crops, respectively; (2) and (5), supply functions; (3) and (6), equilibrium conditions. Under the assumption that other factor prices are constant, other factors can be employed at optimum levels without cross-effects on production between sectors. This reduces the ϵ_{ij} to cross-elasticities of supply of land between sectors as the prices in the two sectors change, which is shown below.

To obtain the restricted model, the free market model is modified to incorporate the fixed price and fixed land provisions of the corn program. The support price is incorporated by replacing equation (3) with the parametric restriction

$$P_1 = \overline{P}_1, \tag{3a}$$

which becomes the equilibrium condition for corn. This is equivalent to a product demand of infinite elasticity to producers and a supply of infinite elasticity to consumers at the support price. Production no longer equals consumption unless the government is able to adjust production to consumption through the control of land. Otherwise the government buys or sells corn to make up the difference. Although the fixed price can be enforced only if the quantity demanded at $\overline{P}_1$ is less than production plus carryover stocks, the market situation for corn was well within this range from 1961 to 1966.

Fixed land is incorporated by a modification of equation (2). At any point

$$X_1^s = A_1 Y_1, \tag{7}$$

where A_1 is the quantity of land and Y_1 is yield per unit of land. In the neighborhood of X_1^s,

$$\epsilon_1 = \epsilon_{a1} + \epsilon_{y1}, \tag{8}$$

where ϵ_{a1} is the elasticity of supply of land and ϵ_{y1} is the yield elasticity, both with respect to the price of corn. With these two equations, the free market supply of corn can be interpreted as the product of a land supply and a yield function,

$$A_1 = C_{a1} P_1^{\epsilon_{a1}} P_2^{\epsilon_{12}} \tag{9}$$

and

$$Y_1 = C_{y1} P_1^{\epsilon_{y1}}, \tag{10}$$

where C_{a1} and C_{y1} are constants. The cross-elasticity term appears only in the land supply equation. Using (9) and (10), equation (2) in the free market model is written

$$X_1^s = C_{a1} C_{y1} P_1^{(\epsilon_{a1}+\epsilon_{y1})} P_2^{\epsilon_{12}}. \tag{2a}$$

Under the assumption that the yield function is not affected by the program,[8] specification of the restricted supply surface for corn reduces to replacing equation (9) by

$$A_1 = \overline{A}_1. \tag{9a}$$

Under this condition the restricted supply of corn is

$$X_{1r}^s = \overline{A}_1 C_{y1} P_1^{\epsilon_{y1}}. \tag{2b}$$

Figures 1 and 2 illustrate the model. The curves $D_k(P_{ij}$ or $\overline{P}_1)$ and $S_k(P_{ij}$ or $\overline{P}_1)$, i,j, $k=1,2$, trace the paths of the free market demand and supply functions at the corresponding prices in the other market. The curve S_{1r} represents the restricted supply of corn, equation (2b).[9]

In the analysis the actual production, consumption, and price of corn and other crops are assumed to represent the restricted equilibrium under the program. In Figure 1 production of corn is X_{12} and consumption is X_{11} at the support price $\overline{P}_1$.[10] In Figure 2 production equals consumption of other crops at X_{21} with the price of P_{21}.

In the free market model the equilibrium condition and land supply equation for corn change. The equilibrium condition requires that production equal consumption of corn. The land supply equation for corn is estimated under the assumption that producers have adjusted desired land use to the support price.[11] Under this assumption production would expand to X_{13} in Figure 1 at the price $\overline{P}_1$ if there were no restrictions on production. With the release of the support price this represents an excess supply of corn. As the price of corn falls the price of other crops falls with it until both sectors reach free market equilibrium at (X_{10}, P_{10}) for corn in Figure 1 and (X_{20}, P_{20}) for other crops in Figure 2.

---

[8] It is generally held that retired land on average is of lower quality than producing land, but there is disagreement on the extent of this difference; e.g., see [6, p. 5]. The effect of such a difference is that, under the assumption that equation (10) is independent of land use, the model will overestimate the quantity and underestimate the price of corn in the free market.

[9] The remaining curves are explained at a later point.

[10] Consumption of corn exceeded production by an average of 227 million bushels from 1961 to 1966. However, the model is also valid when production exceeds consumption.

[11] The decline in the real price of corn over time suggests that the corn base is at least as great as desired free market land use at the support price.

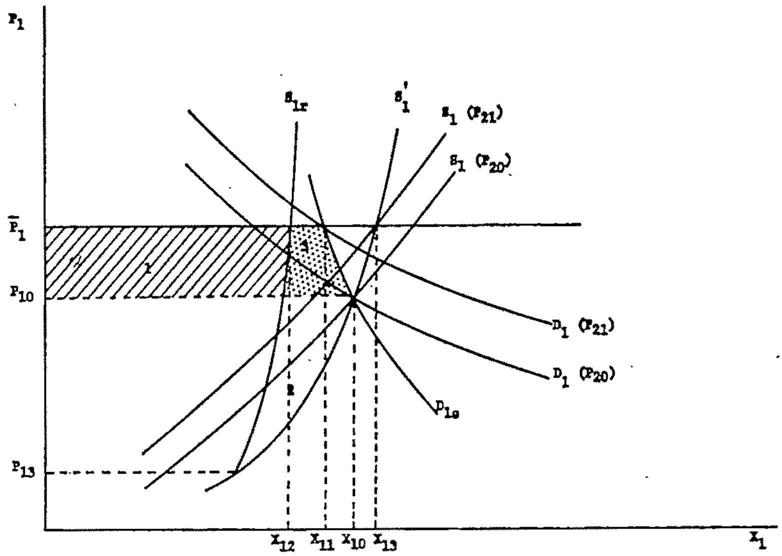

Figure 1. Illustration of sector 1, corn

Welfare Analysis

The objective of the welfare analysis is to estimate the change in the distribution of income and the loss of real income resulting from the restrictions imposed by the corn diversion program. Four welfare quantities are computed in the analysis: consumer costs, producer benefits, net welfare costs, and the change in variable factor income. Consumer costs is the loss of satisfaction to consumers because of the program.[12] Producer benefits is the increase in rent received by land, the restricted factor of production.[13] Under an ideal transfer program consumer costs would equal producer benefits. However, the program restricts the use of land and fixes the price level, which causes resources to be used less efficiently. Therefore, land receives only part of the loss to consumers. The

[12] Consumers include all persons who use agricultural crops and who pay taxes in support of the program.

[13] Land is the restricted variable of the program; strictly speaking, producers are landowners. However, operator labor in many cases is a fixed factor and, although not restricted by the program, may share in producer benefits. Vermeer [12, 13] has found that tenant farmers on crop share leases share in direct government payments in proportion to their share of the crop.

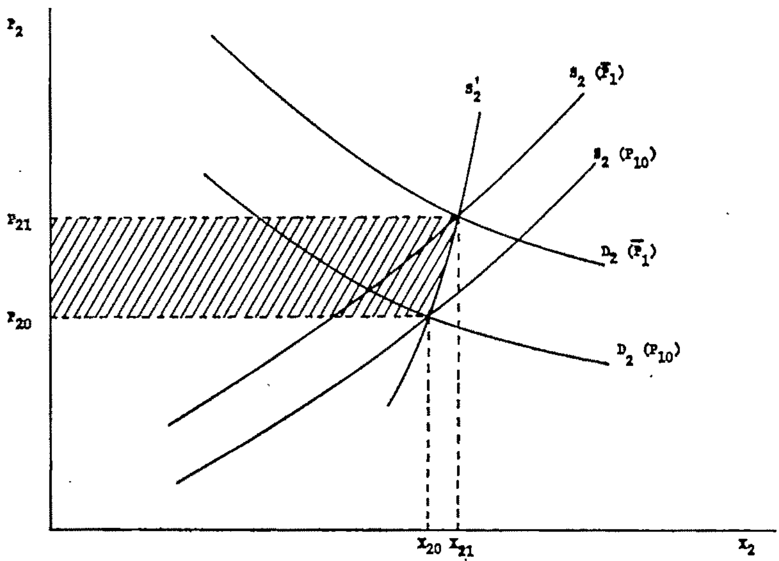

Figure 2. Illustration of sector 2, other crops

remainder is the net welfare cost, that amount lost through inefficient resource use. The change in variable factor income measures the total change in income received by variable factors of production.

The four welfare quantities include changes in consumer or producer surplus.[14] This requires the questionable but necessary assumption of constant marginal utility of income on the demand and supply functions.

The three-dimensional model is reduced mathematically to two dimensions in order to derive the welfare quantities. The curve S'_2 in Figure 2 is the trace in the X_2, P_2 plane of the locus of equilibrium points in sector 2 as P_1 varies. Equilibrium in sector 2 implies specific movements along the demand and supply function for corn. To obtain these movements the equations of sector 2, equations (4), (5), and (6), are solved to obtain P_2 as a function of P_1. This function is substituted for P_2 in the demand and supply functions for corn, equations (1) and (2), to obtain the two-dimensional functions represented by D_{1r} and S_1' in Figure 1. These two curves trace the path in the X_1, P_1 plane of their respective functions under the condition that sector 2 is in equilibrium.[15] The derivation of the welfare effects is based on these reduced functions. Although the quantities are defined for each sector, only the total quantities have direct relevance. It should be recalled that the implicit rest of the economy sector is the base on which the definitions rest.

In sector 1 consumer costs are the change in consumer surplus, plus direct government payments to producers which consumers pay as taxes, minus a pure transfer between consumers and the government because the government sells corn from stocks at a price other than the free market equilibrium price. The change in consumer surplus is the sum of areas 1 and 3 in Figure 1, i.e., the change in satisfaction due to a change in price. Direct government payments are the land and subsidy payments for land diversion, which averaged \$834 million during 1961 to 1966. The pure transfer, offsetting part of area 3 in Figure 1, is

$$T = (\overline{P}_1 - P_{10})(X_{11} - X_{12}). \tag{11}$$

Producer benefits from corn are the sum of the change in producer surplus and direct government payments. The change in producer surplus is area 1 minus area 2 in Figure 1. Area 1 is the part of the loss to consumers that producers receive through the change in the price of corn. Area 2 is the loss from inefficient resource use because of the restriction on land use. This area measures, not the loss from inefficient use of resources to produce corn, but the total loss to the economy from the inefficient use of resources because of restricting the use of land to produce corn.

Net welfare costs in sector 1 are consumer costs minus producer benefits, or the sum of areas 2 and 3 in Figure 1 minus equation (11), the pure transfer. The change in variable factor income in sector 1 is the change in gross income from corn minus the change in producer surplus.

In sector 2, under the assumption of free adjustment to restrictions on corn, net welfare costs are zero.[16] The total loss from inefficient resource use is measured in sector 1, area 2, in Figure 1. The change in consumer surplus that is not captured by producers is also measured in sector 1 because the demand function takes account of the change in the price of other crops, area 3 in Figure 1 minus equation (11).[17]

Since welfare costs are zero in sector 2, consumer costs equal producer benefirs, the shaded area in Figure 2. The change in variable factor income from other crops is the change in gross income minus producer benefits.

To obtain the total effects of the voluntary retirement program, the welfare quantities from both sectors are summed. Total consumer costs, producer benefits, and change in variable factor income are the sums of their respective components in sectors 1 and 2. Total net wel-

[14] See Mishan [5] for a more complete discussion of producer surplus. Producer surplus as used here corresponds to Mishan's economic rent, although operator labor receives part of the transfer in the periods considered here (see footnote 13). See Marshall [4, pp. 124–33] for the original development of consumer surplus, and Harberger [2] for a fuller treatment.

[15] The procedure was suggested by A. C. Harberger. It is developed more fully in Hushak [3]. In Figure 1, S_{1r} lies to the left of S_1' because land use is fixed on S_{1r} and is less than land use on S_1' above P_{12}.

[16] In the present case sector 2 adjusts by moving along its demand and supply functions as other crops are substituted for corn. However, even if diverted corn land were used for other crops and the supply function for other crops shifted outward, there would be no welfare costs in sector 2 because sector 2 is adjusting freely to the corn program. The reduction of the model to two dimensions, keeping sector 2 in equilibrium, has the effect of collapsing the net welfare cost of the program into sector 1.

[17] Technically, the part of area 3 to the left of X_{12} is due to inefficient resource use but is included with the change in consumer surplus for simplicity.

fare costs are equal to net welfare costs in sector 1 since they are zero in sector 2.

Results

The program is analyzed on the basis of its estimated effects on the market, not on the basis of its stated objectives. The data are assumed to represent the restricted equilibrium point under the voluntary program.[18] In sector 1 the support price, hereafter referred to as the average price under the program, is defined as the average price lagged one year received by producers for corn from 1961 to 1966.[19] Production is actual average output of corn for grain during the period. Restricted acreage is actual average acreage harvested for grain, from which yield can be derived. Consumption is defined as production plus average government stock disposal.[20]

In sector 2 the index of prices received by farmers for all crops (1910–14=100 using a July 1 to June 30 crop year) is adjusted to eliminate the price of corn to get an index of prices received for other crops,

$$I_2 = \frac{I - w_1 I_1}{w_2}, \tag{12}$$

where I, I_1, and I_2 are the index numbers of all crops, corn, and other crops, respectively, and w_1 and w_2 are the value shares of corn and other crops, $w_1+w_2=1$. The other crop price is an average of I_2 lagged one year. Production of other crops is an average of

$$X_2 = \frac{\text{value of all crops} - \text{value of corn}}{I_2}. \tag{13}$$

Estimates of the parameters and free market land use are presented in Table 2. The demand parameters are derived from previous research on the demand for agricultural products.[21] The supply parameters are estimates obtained from time series regressions of yield and land supply equations for corn and other crops. The yield and land supply equations for other crops are derived in the same way as they were for corn in equations (9) and (10). The short-run parameters in Table 2 are estimates from equations using price variables lagged one year. The medium-run parameters are estimates from equations using three-year weighted average lagged prices. The free market land use estimates are based on regressions for periods of unrestricted land use and an examination of the trend in land used for corn production. The lower and upper bounds represent limits that are likely to contain the true parameter values.[22]

The cross-elasticities are assumed to be proportionally related to own-price elasticities to reduce the number of parameter combinations. Under the assumption that the demand functions are homogeneous of degree zero in income and prices, the relation $\eta_{12}=-0.2\eta_1$ was derived at $\eta_1=-0.5$ and was assumed to hold for all values of η_1.

The Slutsky symmetry condition gives the relation

$$\eta_{21} = \frac{X_1 P_1}{X_2 P_2} \eta_{12}$$

Table 2. Parameter and land use estimates, 1961–1966

	Lower bound	Short run	Medium run	Upper bound
Corn				
Demand elasticity	−0.3	−0.5	−0.5	−0.7
Yield elasticity	0.01	0.1	0.1	0.2
Land elasticity	0.1	0.2	0.4	0.8

Other Crops				
Demand elasticity	−0.2	−0.4	−0.4	−0.7
Yield elasticity	0.01	0.1	0.1	0.2
Land elasticity	0.1	0.2	0.4	0.8

[a] Estimated free market land use for corn at the 1961 to 1966 average price of corn.

[18] The data are from [9, 10].

[19] The average price received is used rather than the government support price because it is the price actually achieved in the market by the program. The average price received is referred to as the average price under the program to prevent confusion of this price with the announced support price.

[20] This definition of consumption is equivalent to total disappearance of corn, i.e., domestic consumption, exports, and waste or loss.

[21] No attempt is made to cite a complete list of demand studies. The most frequently used study was Brandow [1].

[22] The analysis is restricted to shorter-run periods because of an almost complete lack of knowledge of the long-run supply parameters. As many as four values of each parameter were used to see how sensitive the model is to changes in parameter values. It is not possible to make a probability statement about the lower and upper bounds because of the way in which the parameter values were derived. The demand parameters were derived from a synthesis of the results of demand studies. High multicolinearity resulted in high standard errors for the coefficients of the supply equations. It was necessary to base the supply parameter estimates on the results of regressions using varying sets of predetermined variables. Generally, the estimates of elasticity coefficients were quite stable as the set of predetermined variables other than P_1 and P_2 were varied.

under the assumption that the term involving income elasticities is zero. On the supply side the relations $\epsilon_{12} = -0.7\ \epsilon_{a1}$ and $\epsilon_{21} = -0.125\ \epsilon_{a2}$, where ϵ_{a2} is derived in the same manner as ϵ_{a1}, were derived at the short- and medium-run estimates of ϵ_{a1} and ϵ_{a2} and were assumed to hold for all values of these parameters.

The model is solved and the welfare computations are made for all possible combinations of the parameter values in Table 2. Two sets of results are presented. The set in Table 3 is estimated under the assumption that the government does not dispose of stocks under free market conditions. The set in Table 4 is estimated under the assumption that the government disposes of stocks in the free market at the same rate that it actually disposed of them under the program in the 1961–1966 period. Stock disposal averaged 227 million bushels during this period.

In Table 3 the short- and medium-run estimates show that the price of corn increases about 2 percent to $1.13 from the $1.11 average price under the program, with a range of $0.91 to $1.26. The short- and medium-run estimates indicate corn production increases about 5 percent over restricted production of 3,852 million bushels, while the range is 2 to 14 percent.

The short- and medium-run estimates of the price of other crops show an increase of less than 1 cent per unit over the average price under the program of $2.50. The estimates range from $2.46 to $2.53. Production of other crops shows little change from production under the program of 6,730 million units, with maximum changes of less than 0.5 percent.

As stated above, only the totals of the welfare quantities are directly relevant. The components are presented in Table 3 to show the composition of each quantity. Total consumer costs range from $99 million to $1,959 million, with the short- and medium-run estimates around $740 million. The short- and medium-run estimates are 3.5 percent of the $21,382 million average value of all crops consumed, while the maximum is over 9 percent.

The short- and medium-run estimates of total producer benefits are about $720 million, with a range of $78 million to $1,746 million. The short- and medium-run estimates are about 3.5 percent of the $21,129 million average value of all crops produced,[23] while the maximum is over 8 percent.

Net welfare costs of the program are small with a maximum of $261 million, about 1 per-

[23] The values of corn produced and consumed differ because of stock disposal by the government.

[a] These two columns represent extreme parameter points. A_1 is land use for corn.
[b] These are extreme values, presented only when they lie outside the values in columns 2 to 5.

cent of the value of crops consumed. However, welfare costs do reach about 10 percent of consumer costs; i.e., as much as 10 percent of the income transferred from consumers to producers is lost through the program restrictions. The change in variable factor income is a decline of $48 million to $421 million, centering around $200 million. These quantities are relatively small because the elasticities of supply and demand are small, which implies that relatively large income transfers can be realized with small resource distortions.

The results in Table 4, estimated under the assumption of 227 million bushels of stock disposal per year in the free market, differ from those in Table 3 in expected directions. Free market outputs and prices of corn and of other crops are lower than in Table 3, while consumer costs and producer benefits are larger. No stock disposal adjustment is needed because stocks are outside the model; i.e., the demand for corn is net of stock disposal. Net welfare costs and the decline in variable factor income are lower because the relative resource distortion is less than in the previous case. This is a short-run only case because stock disposal will last no longer than government stocks, and government stocks of corn were nearly depleted by the end of the 1966 crop year.

Administration and Storage Costs

Administration costs of the Feed Grain Pr gram averaged about $34 million from 1961 t 1963 [7, p. 13]. The share of corn in this co is probably about $30 million. If administratio costs averaged $30 million over the 1961–196 period, all estimates of consumer costs and n welfare costs in Tables 3 and 4 are increase by this amount.

The incorporation of storage and handlir costs of government stocks into the model d pends on acceptable methods of disposal. also depends on the substitution between go ernment and private stocks. For simplicity i illustrating alternatives, it is assumed th private stocks do not depend on governmer stocks, although this dependence exists.

As of 1960 annual storage costs for cor averaged about 14 cents per bushel.[24] Valuin corn at $1.00 per bushel and assuming a 5 pe cent return on capital, there is an addition cost of 5 cents per bushel, or a total annu

[24] This estimate is derived from data on storage costs [8]. Commercial storage costs are 10 cents per bushel pl 8 cents for handling, shrinkage, and return on investmen or 18 cents per bushel. Costs in government-owned stora facilities are 5 cents per bushel plus 5 cents for handlin shrinkage, and return on investment. The arithmetic mea of these two estimates is 14 cents per bushel.

cost of 19 cents per bushel. On October 1, 1961, the Commodity Credit Corporation (CCC) owned 1,371 million bushels of corn. Had these stocks been stored for the entire period, the annual costs would have been $260 million. Under the voluntary program the CCC held an average of 780 million bushels during the period, resulting in storage costs of $148 million.

The estimates in Table 4 are not affected because the free market has the same level of stocks that existed under the program. In Table 3, if the CCC had destroyed its stocks with a free market as of October 1, 1961, consumer costs and net welfare costs would be increased by $148 million, the cost of storing the average quantity of stocks owned by CCC under the program during this period. On the other hand, if CCC had to store all the stocks in a free market, consumer costs and net welfare costs in Table 3 would be decreased by $112 million, the difference in cost between storing all the stocks and average stocks under the program during this period.

Summary and Conclusions

A supply-demand model is used for a welfare analysis of the voluntary corn diversion program. It is a two-sector model, which allows an analysis of the effects of the program on other crops under the assumption that other crop markets are free of restrictions.

This analysis shows that the major effect of the program was on the transfer of income from consumers to producers. The price of corn during this period was near free market levels, output was reduced sufficiently to dispose of government stocks accumulated during the 1950's, although at a cost to consumers of the order of $3.70 per bushel sold from stocks.

The resource distortions were small because of the relatively inelastic demand and supply functions. Net welfare costs reach a maximum of about 10 percent of the total income transfer but are probably closer to 3 percent.

The addition of administration and storage costs modifies these results, however. Administration costs are about 3 percent of producer benefits at the short- and medium-run estimates, which increases welfare costs from 3 to 6 percent of the income transfer. Storage costs of government stocks have a positive or negative effect, depending on alternatives. They modify the results from showing a net welfare gain from the program to welfare costs of over 50 percent of the additional income received by producers at the short- and medium-run estimates.

A Model of Competitive Behavior in Food Industries*

C. R. Handy and D. I. Padberg

While conventional industrial organization theory has been used to explain behavior of the food distribution oligopoly, a more careful analysis shows its behavior tendencies to be basically different from the manufacturing oligopoly. The larger distribution firm tends toward price competition while the smaller tends toward nonprice competition. The interaction between manufacturing and distribution oligopolies in the food industry provides a unique balance between progressiveness and economy which is not available in industries where the distribution oligopoly has not developed. This different consequence of large firms brings up some basic questions about antitrust objectives and philosophy.

There is a need for a better map to identify main directions and milestones of competitive activity in food industries. Typically, economists apply general industrial organization theory and hope for the best. That is not sufficient. Industrial organization theory is designed for a distributive channel dominated by a manufacturer. No model has been developed concerning behavior within a channel dominated by a distributor. The "big business" distributor occurred only infrequently outside food industries until recently. The economic characteristics of the large distributor have not been extensively studied.

In addition, general industrial organization theory as typically applied has had little success in accommodating the usual conflict between efficiency-oriented performance norms and performance dimensions having to do with progress and qualitative change. This conflict has prevailed because no one was willing or able to determine how much emphasis should be given to efficiency as against progress. As a result, Bain and others list both progress and efficiency norms as aspects of performance. While that may be sensible, it is impossible to apply to any particular firm. Organization imperatives for physical efficiency are different from those of product progress. This model accommodates this conflict by presenting a manufacturing-distribution channel specialized toward economy and process innovation separate from but competing with another emphasizing product progress. Here consumers, by allocating their purchases between the two channels, can select their preferred balance of emphasis.

* Developed from work conducted at Cornell University under Hatch Project 007, Organizational Structures for Marketing Processed Fruit and Vegetable Products.

C. R. Handy *is agricultural economist with the Marketing Economics Division, USDA*. D. I. Padberg *is associate professor of marketing at Cornell University.*

The food industries make a good laboratory for studying industrial organization. As well as being the oldest and biggest industrial complex, it is clearly the most structurally mature. Its size allows a degree of specialization among structural configurations not well developed in most other industries. Its size and proximity to consumer interests have stimulated constant analysis which creates a massive body of data.

The National Commission on Food Marketing assembled a useful stock of data on this industry. We have more data than understanding. This situation offers an opportunity to revisit some of the primary questions concerning industrial organization. This paper will undertake the task of extending and modifying standard conceptual framework in light of observations available.[1]

The conceptual framework we use is an outgrowth of Bain's work. Major extensions or changes are the following:

(1) A model of bilateral interaction (large manufacturer vs. a large distributor) is developed.
(2) Functional specialization among manufacturing and retailing substructures[2] is recognized.

Other changes will be noted: Extensive use is made of multidimensional performance characteristics, and the model is not limited to single-product markets; multiproduct manufacturers and distributors and the addition and dropping of products are comfortably accommodated.

[1] These data are not presented as a test of the hypothesized model. In fact, the model was developed from these observations.

[2] "Substructure" refers to a group of firms within an industry structure that portray similar market behavior. Any sharp boundary between substructures tends to be blurred by exceptions. Traditional discussion of "oligoply core" and "competitive fringe" is an example of substructure recognition.

The Model

This model is specified schematically rather than quantitatively. It depends upon the identification of substructures within the food distribution system. Behavior patterns ascribed result primarily from the tendency toward specialization by the various substructures. The structural elements of this model include:

(1) A food manufacturing oligopoly core.
(2) A large fringe[3] of small- and medium-size food manufacturing firms.
(3) A food distribution oligopoly core (large food chains).
(4) A large fringe of small-and medium-size food retailing firms.

Alignment of these substructures is of particular interest. Oligopoly core manufactueres tend to work most directly with fringe distributors. This combination constitutes a channel that emphasizes innovation and progress as regards the character of the product and services. It is on this basis that products within this channel are differentiated. Oligopoly core distributors tend to emphasize private label programs; hence, they are best served by the fringe processors. This substructure combination is a separate channel organized to emphasize physical efficiency and price competition. The drive for physical efficiency directs innovative activity within this channel toward process development as opposed to product development. Products within this channel tend to be differentiated on a price basis.[4]

Substructure specialization

The primary direction of competitive behavior results from functional specialization within each substructure. The character of this behavior pattern emerges as the organizational features of the various types of firms are identified.

Core manufacturers.—These food manufacturers are large firms, usually diversified into many products. Brands are important to them. A major part of their competitive strategy revolves around improving brand meaning and impact. Product and market research certainly fit into this category. Advertising, promotion, and new product introduction skills also pertain to brand selling. These functions are expensive and probably have significant scale economies. Therefore, larger firms have a competitive advantage in the introduction and marketing of new products.[5]

Core distributors.—The primary competitive advantage of core distributors is their preretailing operations. All core distributors have warehouses, manufacturing plants, quality control laboratories, and computer-controlled logistic systems. Please note that the preretailing advantages of the core distributor structure pertain to matters of cost and efficiency, not product quality. In pressing the economy alternative, larger distributors tend toward lockstep merchandising plans favoring high volume standard quality products. These private-label products of core retailers are some of the industries' most extensively differentiated products. However, they convey a different meaning from most differentiated products. Private-label products represent standard quality at minimum cost. Their appeal is economy.

Fringe manufacturers.—These many small- and medium-size food processors have little or no marketing capability. If they have a brand, it means little to consumers. Brand development costs are exorbitant for their small volume. They find private-label business very compatible with their physical structure and capabilities. Private-label programs enable them to specialize in the physical functions of food processing—their primary competitive advantage.

Fringe distributors.—Small- and medium-size distributors do not have the preretailing cap-

[3] The use of the term "fringe" needs clarification. Previous studies have rarely developed any precise definition for this term, but it has come to imply a small number of small firms contributing a small share of market volume. In this study the substructure boundaries are drawn on the basis of specialized behavior patterns. It turns out that the "small firm substructure," here called the fringe, has a large number of firms and contributes the majority of industry output.

[4] While the basis for differentiation differs, there are of course instances within both channels where differentiation is more illusionary than real.

[5] We do not mean to imply that new products and technology are not developed by fringe manufacturers. Several studies have addressed the relation between innovation and firm size [1, 8, 18, 19]. Measures of innovation include R and D expenditures, output of patented inventions, and the adoption rate of new technology. The frequent conclusion is that no particular advantage seems to rest with large firms. This conclusion says little about scale economies in a market for consumer goods under conditions of general affluence (literally thousands of product alternatives). These conditions require significant introduction and promotion activity. Here large firms clearly have an economic advantage.

abilities of the big chains. Their advantages involve greater merchandising flexibility. Smaller retailers use this flexibility to adapt their stores to the particular needs of communities they serve. The wider variety of more progressive products from core manufacturers fulfills their product and service needs. In competing with the standard offerings of large chains, fringe distributors have become more innovative in store design as well as merchandise variety. In this way, their competitive advantage is compatible with the competitive emphasis of core manufacturers.

This sharp distinction between substructures and channels may seem overdrawn. From whatever vantage point, any careful observer of the large and varied food industries will find several exceptions. Yet, it is useful, in understanding this sector's performance, to know the general and significant rules of its behavior.

Competitive interaction

For most products, core manufacturers and core distributors avoid direct confrontations. While these two major foci of power seek consumer attention and patronage, they do it in different ways. The manufacturing oligopoly stresses product development and is clearly more adept at this function than the distribution oligopoly. The latter is able to dominate the terms of trade for standard products and merchandise them to the public with an economy emphasis through extensive private-label programs. This situation channels the energy of the large aggressive firms toward presenting and accentuating consumer alternatives rather than into a socially expensive and unproductive fight.

Empirical Analysis[6]

The basis for behavior patterns asserted by the model is now identified. In presenting the model as a framework of general tendencies concerning competitive behavior, it is desirable to know the consistency between data and the model and the extent of exceptions.

Food manufacturing

Structure.—There are approximately 30,000 food manufacturing firms in the United States. Within this group the 100 largest firms, which include the largest members of most food processing industries, are defined as the oligopoly core. Each firm within this substructure has assets in excess of $50 million. The fringe substructure consists of the remaining several thousand food processing firms. Of the major four-digit food industries producing primarily consumer products, only cereal preparations, cocoa products, chewing gum, and cane and beet sugar refining do not have a substantial manufacturing fringe. Significantly, private-label sales have been small or nonexistent in these industries. The existence of a viable fringe substructure would likely increase the actual or potential supply of private-label products and thus improve performance in the economy dimension.

Core firms are growing at a slightly faster pace than the food industry as a whole. The 100 largest firms accounted for 42 percent of total food industry value added in 1954 and for 46 percent in 1963 [15, p. 21]. The increased concentration of value added is due more to diversified rather than horizontal growth of large food manufacturers. The top four positions of five-digit food product classes held by the 100 largest food manufacturers increased from 63 percent in 1954 to 70 percent in 1963. In addition, analyses by Michael Gort [6, p. 68] and the Food Commission [15, pp. 43–58] indicate that within this large firm group, diversification is positively correlated with size of firm. This is consistent with the functional orientation of large firms.

Mergers have played an important role in this diversification process. Between 1960 and 1965 the 50 largest food manufacturers completed 294 food and nonfood acquisitions. Of these, 64.9 percent were conglomerate mergers; 18.4 percent were horizontal; and 16.7 percent were vertical [15, p. 111]. From 1950 to 1965 the 50 largest firms increased their assets by $8,203.4 million. Measured in 1965 dollars, $2,279.7 million, or 27.8 percent of this growth, resulted directly from acquisitions. Over 70 percent of asset growth resulted from internal expansion.[7]

Rather than accumulation of assets, mergers have primarily facilitated the expansion of large firms into additional industries. Table 1 shows that between 1950 and 1966, 25 leading food manufacturers entered a new type of food processing business 108 times. Ninety-six of these instances, or almost 90 percent, resulted

from mergers. Consolidated Foods was the most merger-prone firm with 11 acquisitions, followed by Beatrice Foods and PepsiCo.

Market behavior.—Data generally support the concept of functional specialization within each substructure. Most core manufacturers who traditionally received a large percent of sales from standardized commodities have over the past years drastically cutrailed these activities and shifted toward marketing specialized consumer products.[8] Accompanying this transition has been an increase in the number of products sold per manufacturer. For 88 large food manufacturers, *Progressive Grocer* calculated an average of 111 products sold per manufacturer in 1964, compared with an average of 73 items in 1959.

Several costs are associated with marketing strategies emphasizing new products. One cost factor is a high rate of product turnover. Since 1959, each of the 88 large firms mentioned above introduced an average of 45 new items and dropped an average of 7 items. As an example, annual reports indicate that from 1955 to 1963 Quaker Oats introduced 37 products while withdrawing 17 products from distribution.

Another cost factor is extensive product and market research necessary to support product innovation activities. In 1954, eighteen large food manufacturers each averaged $1.4 million, or 0.5 percent of sales, for product and market research. By 1964 these same firms averaged $3.3 million, or 0.9 percent of sales, for this activity. Most new products undergo test-marketing before they are introduced. For 72 new products studied this activity cost an average of $248,000 per product [13, pp. 22, 31, and 35]. Additional expenses associated with product development are the time and risk factors. For 127 distinct new products studied, an average of 27 months was required to achieve full distribution from the time formal research began. The study further showed that of 124 new products introduced by 16 core manufacturers, only 61 percent reached full distribution [13, p. 39].

Advertising and promotion are intricate facets of brand selling. It is well-known that advertising expenditures are highly concentrated among the largest firms. Estimates of the share of food industry advertising expenditures accounted for by the 50 largest food manufacturers range up to 80 percent or more [15, p. 65). In 1966 food manufacturers with assets of $50 million and over averaged 3.5 percent of sales for advertising; firms with assets below $50 million spent an average of 0.9 percent [20, p. 21].

The movement of advertising expenditures over time indicates that functional specialization among food manufacturing substructures has increased. Table 2 shows that from 1954 to 1965 advertising as a percent of sales has remained almost constant for fringe manufactures (assets below $50 million), indicating their continued emphasis on physical functions of production rather than any attempts to compete with large firms in the area of brand development.

Fringe manufacturers instead rely heavily on the private label programs of wholesalers and retailers for market outlets. Data collected by the National Commission on Food Marketing

[8] In 1949 bread contributed 71 percent of total sales for Contineta1 Baking compared to 51 percent in 1966, while specialty foods increased from 1 percent to 21 percent of total sales. In 1966, three of the four largest milling companies received less than one-third of sales from flour and mill feed; prior to 1950 all flour milling companies had received 80 percent or more of sales from this source. From 1954 to 1966 fluid milk and butter dropped from 53 percent of Beatrice Foods Company's total sales of 32 percent, while specialty food products increased from 19 percent to 38 percent of total sales.

Table 2. Advertising expenditures of food manufacturing corporations as a percent of sales, by asset

Asset size class	Advertising as a percent of sales					
	1954	1958	1959	1960	1961	1965
All food manufacturing corporations	1.8	1.9	2.1	2.2	2.1	2.3
Fringe manufacturers						
0–$ 99,999	0.9	0.9	0.7	0.8	0.8	0.9
$ 100,000– 999,999	1.1	1.0	1.3	1.1	0.9	0.9
1,000,000– 49,999,999	1.7	1.6	1.8	1.8	1.7	1.9
Core manufacturers						
$ 50,000,000–$99,999,999	2.5	2.6	2.5	2.6	2.9	3.2
100,000,000 and over	2.1	2.7	2.9	3.3	3.2	3.3

Source: [21].

indicate that the output of small fruit and vegetable processors averaged 70 percent private label [11, p. 191]. Less than 4 percent of large bakeries' volume consist of private label, while this constitutes a much larger proportion of the smaller bakers' volume [12, p. 68]. In addition, several large dairies report only about 1 percent of their fluid milk volume is private label [10, p. 144].

On the other hand, core manufacturers have experienced a substantial increase in advertising expenditures to an average of over 3.2 percent of sales in 1965. This reflects the movement of core manufacturers away from standardized commodities toward greater emphasis on product development and branded consumer items. Buzzell and Nourse [3] document the source of major product innovation in 21 food categories. Their chronology is divided into four periods: early development, prior to 1900; pre-World War II, 1900–1938; World War II, 1939–1945; post-World War II. The authors conclude:

> Comparison of each period with earlier periods clearly shows the shift from individual inventors and small companies to large food processors as the primary source of new products . . . the dominance of the large firm is clear cut after 1960. Large processors introduced all nine of the product innovations between 1960 and 1964 . . . [3, pp. 87 and 91].

Competitive behavior of core and fringe manufacturers is further contrasted by observing changes that occur in products of small firms acquired by large conglomerate firms. Table 3 indicates that in the postwar period, brands of acquired firms receive substantially greater advertising support than before the merger. Sixty-five brands of 39 companies received almost double the advertising support in the first full year after acquisition than they had received in the period immediately prior to the acquisition. These data indicate that the cost of continually developing and introducing new products precludes this activity for most noncore manufacturers.

Food distribution

Structure.—Core distributors are defined as the 10 largest retail food chains and are called national chains even though none operates in all metropolitan markets. In 1968 these firms had about 12,700 grocery stores and approximately 30 percent of total U.S. grocery store sales [4, p. 12].

Successful fringe distributors, reflecting their merchandising expertise, tend to have larger, higher volume supermarkets than do core distributors. Only two of the top 10 chains had average supermarket sales of $2,000,000 or more in 1968, while 55 of the 11–100 largest chains had average supermarket sales of this size [4, pp. 12–13]. A tabulation by *Chain Store Age* lists 50 local chains, ranging in size from 4 to 22 supermarkets, that had average supermarket sales between $2,000,000 and $4,500,000 [4, p. 14].

Evidently, consumers' desire for a variety of product-service combinations precludes either core or fringe distributors from dominating most local markets. For 22 metropolitan areas studied, the four largest firms were almost evenly distributed between core and fringe firms—2.1 to 1.9 [5, pp. 20–26]. In a study of 218 local markets the 20 largest food distributors experienced a net decline in market position between 1954 and 1963, while 228 local firms in these markets had a net increase in market position [14, p. 53]. Firms of all sizes experience great difficulty in maintaining local market shares above 20 to 25 percent. Between 1958 and 1963 the number of instances in which local and national firms had market shares of 20 percent or more in 218 markets dropped from 71 to only 51 [14, p. 53]. Core

Table 3. Changes in advertising support for brands acquired by large food manufacturers, 1950–1964

Year	Network T.V.	Spot T.V.	Magazines	Newspapers	Total
	millions of dollars				
Year prior to acquisition	5.4	7.9	6.2	3.2	22.7
First full calendar year after acquisition	7.9	17.1	8.2	9.8	43.0

Source: [15, p. 126].

distributors have grown primarily by expanding into additional market areas. In 1948, 9 leading food chains operated in a total of 392 metropolitan areas, while in 1963 these firms operated in 518 metropolitan areas [14, p. 161].

Market behavior.—Core distributors have a comparative advantage in preretail operations which are subject to significant economies of scale. Most warehouse economies are realized by operations of $100 million or more annual retail sales. However, to obtain available economies of manufacturing and private-label operations, annual retail sales of over one-half billion dollars may be necessary [14, pp. 52, 228].

The close association between core distributors and manufacturing and private-label operations further indicates substructure specialization. In 1963 the 8 largest distributors accounted for over $1.2 billion or about 68 percent of the value of food products manufactured by the 40 largest chains, which in turn account for about 90 percent of all food manufactured by distributors [14, p. 76]. In addition, Table 4 indicates that core distributors manufacture a much wider variety of food products than smaller chains. Even when purchasing rather than manufacturing private-label items, core retailers find that to maintain adequate control they must develop detailed product specifications, maintain quality control laboratories, and develop package and label design. Substantial volume is necessary to support this activity.

Domination of private-label sales by core distributors is apparent from Table 5. Total U. S. private-label movement through wholesale organizations for nine product groups is divided by type of distributor. In 1964 chain warehouses and affiliated and independent wholesalers had private label sales in these products totaling $2.2 billion. Corporate food chains accounted for 88.6 percent of this total,

Table 4. Average number of food products manufactured by 40 largest chains, 1960–1963

1963 rank	Average number of food products (five-digit) manufactured during:					
	1930	1940	1950	1954	1958	1963

[a] Percentages may not add to 100 due to rounding. Source: Computed from Tables 2–8 through 2–11 in [16, pp. 20–22].

compared with approximately 47 percent of total grocery store sales.[9] No study has directly estimated the percent of total private-label sales accounted for by the top 10 distributors. A 1962 Federal Trade Commission study, however, shows buyer concentration in the frozen fruit and vegetable industry by type of buyer and type of brand. In 1959 the 10 largest (core) chains accounted for 34 percent of all frozen fruit and vegetable sales by all food stores. In contrast, these 10 chains purchased 61 percent of the products sold under retailers' brands (private label), while accounting for only 20 percent of the products sold under manufacturers' brands, [14, p. 72].

Expertise in preretail operations results in lower store-door costs for core distributors. Table 6 indicates that national chains enjoy 2.4 to 3 percent lower merchandise cost than do fringe distributors. Prices were also compared by type of label for 10 products, for each of which private label items were less expensive than comparable advertised brands. The price difference averaged 20 percent [14, p. 137]. These factors give core distributors a strong base for merchandising their economy appeal.

Fringe distributors are able to overcome much of the core distributors' preretail cost advantage by more effective performance at the retail level. Progressive fringe distributors rely on unique store decor, highly motivated personnel, and innovative merchandising pro-

[9] Food chains' share of private label sales is biased upward, especially for dairy and bakery products, since purchases by affiliated and unaffiliated independent retailers directly from manufacturers that bypass wholesalers are not included.

Table 6. Store-door cost indexes by type of organization (national chain price = 100)

Product type	National chains	Local chains	Affiliated independents	Unaffiliated independents	Food discounters[a]
Weighted:					
Meat......	100.0	99.7	103.9	101.8	108.0
Produce....	100.0	108.8	105.5	98.0	101.7
Grocery....	100.0	101.5	102.3	101.7	100.4
Nonfood....	100.0	104.3	103.3	105.8	103.9
Total	100.0	102.5	103.1	102.4	102.4

grams. *Progressive Grocer's* "store of the month" award for unusual creativity and leadership in some aspect of supermarket retailing invariably goes to a small- to medium-size independent or local chain. Empirical evidence of superior efficiency with which fringe distributors perform the retail function is presented in a National Commission on Food Marketing study of two markets, in which all types of fringe distributors had gross margins 2 to 5 percentage points lower than the national chains [14, p. 328]. This superior performance at the retail level reduces the cost advantage of core distributors.

Exceptions

Several questions are left unanswered. Some small manufacturing firms bring out new product ideas. The processes that explain the origin of new product ideas are more complex than current capacity to do research. In today's food market, however, it doesn't matter where new product ideas originate; their market introduction almost always requires the promotional abilities of large firms.

There are industries and products where the dichotomy between economy and product progress channels does not exist. Fluid milk and fresh meat industries are examples. Both have specialized processing industries with oligopoly structures, but the emphasis on product progress doesn't mean much. While separate industries may have inherent differences in potential new product possibilities, this lopsided performance in favor of efficiency at the expense of product progress probably results from rigid product definitions for milk and grades of meat. Canned soup is another example. Here the private-label alternative never developed to any significant degree. This seems to result from the unusually effective cost control in the manufacture and distribution of soup.

Cereal is another exception from the tendencies indicated in the model. Here, again, private label alternatives have never amounted to very much. Performance is lopsided in favor of product progress at the expense of economy. Cost control is certainly not the basis for this exception. High selling costs as well as high manufacturer profits provide plenty of room for the economy emphasis of private label. While private-label cold cereal has been consistently offered at substantial savings, its sales have not taken over 5 percent of industry volume. For some reason the economy appeal means little to most consumers in this particular industry. Probably it is explained by the extensive role children play in the selection and consumption of this product. Response to the economy appeal is probably a rather adult behavior pattern.

While this analysis does not engage all dimensions of the model and some exceptions exist, the case for a strong tendency for substructure specialization is impelling. Large manufacturers have clear advantages in the promotion aspects of new product business. Large distributors evidence a consistent commitment to cost-reducing integration schemes. Results of these activities are carried through to competition for consumer patronage.

Implications

These ideas represent a major reorientation of conventional explanations of industry structure–behavior–performance relationships. The implications of these behavioral tendencies should be developed against two separate points of view: implications for industrial organization theory and implications for the domestic food industries.[10]

Implications for theory

Patterns of economic activity presented here depend upon the following principles:

(1) The market place is a valid reflection of society's preferences among performance goals.

(2) Conflicting performance goals (economy

[10] In addition, implications may be drawn for less-developed countries. A distribution oligopoly with its tendency to emphasize low prices and to develop streamlined and efficient supply systems would seem to have much to offer in situations where productivity is generally low. Research concerning goals for market structure in less-developed countries is proceeding with extremely undeveloped hypotheses. Although virtually no data are available on this subject, we think this hypothesis is worth suggesting.

and product progress) can be achieved in a market economy only if substructures in the system specialize to activities compatible with a particular goal.

(3) Manufacturing oligopoly tends toward nonprice competitive strategies.

(4) Distribution oligopoly tends toward price-competitive strategies.

On the basis of these principles, certain methods or directions of industry analysis seem particularly attractive. In the first place, the firm or industry is not an adequate unit of investigation. If separate industries or substructures specialize in different activities to complement or offset others, the total pattern of interaction and behavior cannot be observed through the study of one industry. This is a substantial basis for the sector approach to economic research.[11]

Secondly, the application of universal performance criteria across all substructures seems inappropriate. While price fixing or false advertising should rightly be illegal per se, there does not seem to be any single norm for criteria such as profit rates or advertising expenditures. Industry analysis should thus give primary consideration to encouraging a competitive environment in which substructures of both channels can compete.

Probably the most unusual aspect of this conceptual construction is the "distribution oligopoly." Such a structure did not exist before this century. It first began to exert influence on food markets around 1920. It is not surprising that this substructure has received little attention in the stream of classical economic literature. On the other hand, it seems compatible with economies having high consumer income and mass production of consumer goods. While distribution oligopolies have achieved their most advanced development in food industries, they now spread far beyond this sector, particularly into the general merchandise discounting field. Distribution oligopolies are probably a structural characteristic of the more mature industry sectors.

Implications for domestic food industries

There are implications for private planning of firms in domestic food industries. Greater specialization seems increasingly likely to accompany the forming of larger firms and more concentrated structures in processing and distribution. This will lead to a condition where all products are differentiated. They will not be all premium products. Oligopoly processors will differentiate premium and progressive products. Oligopoly distributors will differentiate their private labels around the economy image. Products without the powerful differentiating capabilities of one or the other will drop from the market.

The most significant implications for the domestic food industries, however, pertain to public policy. Often antitrust issues in various food processing industries have been addressed with no consideration given to the role of the private-label activity of major distributors. The tendencies toward nonprice, quality-oriented, competitive activities of oligopoly processors have been seen as depriving society of the price-competitive alternative. That the distributive oligopoly provided this alternative was not taken into account. As a result, aggressive antitrust decisions have been handed down in industries where the combined strategies of the whole sector were surprisingly responsive to both efficiency and progress norms.

An interesting case in point is the dairy industry. Merger guidelines for this industry were drawn up in an effort to keep the structure close to the atomistic structure most likely to compete through price [9]. The basis for this policy was drawn from study of structure and behavior of the dairy processing industry. No mention is made of the private-label programs of food distributors. There is no behavior characteristic of this industry that places so important a competitive constraint on dairy processors.

Large processors cannot be expected to seek consumer attention primarily through price. The structural features of the private-label program are superior there. The major processor should use his reasearch and promotion capability to advance product progress qualitatively. Only he can do this. If one were to fault dairy industry performance, it would not be the lack of the price-competitive alternative. That is well-done and widely available. The more serious shortcoming is in the product progress area. The antitrust harassment is probably at cross-purposes with product progress. It leads major firms, with the capability to introduce new products to an affluent society, to diversify out of dairy.

[11] While the theoretical framework underlying industrial organization places considerable emphasis on the market as a unit of inquiry rather than the firm or industry, in application researchers frequently give undue emphasis to structural elements of only one side of the market.

Conclusions

The food industry provides an opportunity without parallel for studying industry structure and behavior. This study suggests a type of market-oriented interaction pattern very broad in scope. This interaction pattern extends beyond the firm or industry. It involves specialization of some industries to offset or complement others. For this reason the full picture of competitive response may not be observed in the study of a few units of the processing-distribution complex. These patterns of specialization and complementarity are necessary if society's multidimension performance goals are to be achieved.

Computing Equilibrium Solutions for Imperfectly Competitive Markets*

YAKIR PLESSNER

In most theoretical as well as empirical studies the conditions of free competition are assumed, and thus conclusions are subject to competitive behavior. In the real world, however, noncompetitive structures are quite common and deserve not less but, from several viewpoints, more attention than competitive ones. Assuming a linear demand system and constant returns to scale and using quadratic programming, it is shown how partial market equilibria for various leading firm and monopolistic structures can be computed. The operational usefulness of such computations is demonstrated via an application to an agricultural industry.

MICROECONOMIC THEORISTS have devoted a great deal of thought to problems of behavior and equilibrium positions under various market structures. The competitive structure has received by far the most attention and research in this direction has attained a high level of sophistication, including the computation of fixed points for competitive economies.

This paper deals only with partial equilibria and uses a more conventional armory. Its main objective is to treat the more neglected but rather common structures of imperfect competition. As Kottke [4] has pointed out, knowledge of equilibrium positions in noncompetitive markets is important in many practical situations and particularly may be very useful in the formulation of economic policy. Kottke mentions quadratic programming as a promising tool, and that is the approach taken here.

We present and discuss the properties of a series of quadratic programming models, each of which represents a particular market structure. We shall show that the solutions obtained in these models are, under certain assumptions, equilibrium solutions for the markets under consideration, and we shall then report the results of applying some of these models to an agricultural industry and present some conclusions that can be drawn from such an application.

Quadratic programming models have been presented and discussed at various levels of generality [2, 9, 10, 11]. Applications, primarily to situations of competition, and recently also to monopolistic structures, are also available [3, 5, 6]. Thus, devoting a paragraph to the competitive case, we shall describe in detail the construction of noncompetitive models. In particular, we focus attention on the leading firm and complete monopoly structures.

In all cases we consider a sector of the economy that produces n goods and is small enough for consumer income and prices of all other goods to be taken as given. In other words, we are solely concerned with partial equilibria. It is also assumed that the production process can be described by linear production activities. We adopt the following notation, using lower case letters to denote column vectors, capital letters for matrices, and Greek letters to represent scalars:

- x = level of output of the n goods;
- b = available quantities of limited (fixed in the short run) production factors, m in number;
- A = input matrix, of size $m \times n$, indicating inputs of the limited factors per unit level of x;
- p = price vector of the n goods;
- c = "variable" costs per unit level of x;
- u = imputed ("shadow") price vector of the limited factors.

It is assumed that price formation[1] in the market can be described by

$$p = a + Dx, \tag{1}$$

where a is an n-vector of constants and D is an $n \times n$ negative semi-definite matrix.[2]

* This study was financed in part by a grant from the Israel Ministry of Agriculture. I am indebted to M. Herz for much of the empirical work, to M. Kohn for the quadratic programming code, and to reviewers of this paper for helpful comments.

YAKIR PLESSNER *is lecturer in agricultural economics at the Hebrew University of Jerusalem.*

[1] The term "price formation" instead of "demand" is used intentionally, since theory teaches that demand is a function in which the quantity of the good demanded depends on all prices.

[2] The matrix D is called negative semi-definite if $(D+D')$ is negative semi-definite. D need not be symmetric; the

The Models

Free competition

We consider K firms which can produce the n goods. Problem I is to find nonnegative vectors x_k, $k=1,2,\cdots,K$ and u which maximize

$$f_1(x_1,\cdots,x_K,u)$$

$$= a'\sum_k^K x_k + \sum_k^K\sum_s^K x_k'Dx_s - \sum_k c_k'x_k - b'u \tag{2}$$

subject to

$$\sum_k A_k x_k \leqq b \tag{3}$$

$$\sum_k Dx_k - A_k'u \leqq c_k - a \qquad k = 1, 2, \cdots, K \tag{4}$$

The first two terms of the maximand (2) represent total revenue, the third term constitutes variable costs, and the last term represents returns to fixed factors. Thus, (2) is the profit function. It is important to note that while u is a vector of returns to the industry as a whole, it is a vector of alternative costs to the individual firm. Hence, the set of constraints (4) requires that marginal costs do not exceed price for any firm and good.

Denoting the maximizing values by $(x_1^0,\cdots,x_K^0,u^0)$, the following results can be proved:[3] (a) $f_1(x_1^0,\cdots,x_K^0,u^0)=0$; (b) for the ith element of x_k, x_{ik}, it is true that $x_{ik}^0>0$ implies that the price of i equals the marginal costs of its production ($p_i=MC_{ik}$) and $MC_{ik}>P_i$ implies $x_{ik}=0$; (c) letting z_k^0 denote the portion of b utilized by firm k, the solution $(\bar{x}_k,\bar{z}_k)$ of the problem

$$\max p^{0\prime}x_k - u^{0\prime}z_k$$

subject to

$$A_k x_k - z_k \leqq 0$$
$$x_k, z_k \geqq 0$$

is such that $\bar{x}_k=x_k^0$, $\bar{z}_k=z_k^0$.[4]

assumption implies that all the diagonal elements are negative, and is necessary to ensure that every local optimum is also a global one. For a more complete discussion see [8, 10].

[3] Detailed proofs can be found in [8, 9]. The proofs are based on the fact that Problem I is self-dual i.e., the shadow prices of (3) equal u^0 and those of (4) equal $x_1^0,\cdots,x_K^0$.

[4] This is the decentralization property.

It follows from the above that (3) and (4) are not just any sets of constraints but rather the usual optimality conditions for competitive behavior. This raises the possibility that problems like Problem I do not have any feasible solutions that are not optimal.[5] The following numerical example helps to resolve such doubts. Let

$$A = \begin{bmatrix} .5 & 1 \\ 2 & .5 \end{bmatrix}, \qquad D = \begin{bmatrix} -.1 & 0 \\ 0 & -.2 \end{bmatrix},$$

$$b = \begin{bmatrix} 2 \\ 3 \end{bmatrix}, \qquad (a-c) = \begin{bmatrix} .05 \\ .10 \end{bmatrix}$$

$$x = \begin{bmatrix} 1 \\ 1 \end{bmatrix}, \qquad u = \begin{bmatrix} 0 \\ 0 \end{bmatrix}.$$

It can be easily verified that (x, u) is feasible and $f_1(x,u)=-.15<0$, which is not optimal.

Leading firm

In order to facilitate discussion of the more complex quadratic programs which follow, we deviate from the above assumptions and notations and resort to the usual classroom analysis[6] of the leading firm structure, using some simplifying assumptions that will enable us to concentrate on the main points.

Consider a single product market. Let ξ_1 be the output of the leader, ξ_2 be the aggregate output of the competitive followers, and $\xi=\xi_1+\xi_2$. Let α_0, α_1 be constants such that

$$\Pi = \alpha_0 + \alpha_1\xi = \alpha_0 + \alpha_1\xi_1 + \alpha_1\xi_2, \tag{5}$$

where Π is the price of the good under consideration. Next, suppose the leading firm enjoys constant returns to scale, so that marginal costs are a constant, γ_1.

Assume that the aggregate supply curve of the competitively behaving firms is given by

$$\gamma_2 = \beta_0 + \beta_2\xi_2, \qquad \xi_2 > 0. \tag{6}$$

From (5), per unit profits of the leading firm are given by

$$\mu_1 = \Pi - \gamma_1 = \alpha_0 + \alpha_1\xi_1 + \alpha_1\xi_2 - \gamma_1. \tag{7}$$

In order to derive the necessary conditions for optimality, we shall now assume that at equilibrium, $\xi_2>0$. This assumption, to be dropped later, is made to avoid complications

[5] I am indebted to D. Levhari for calling my attention to this apparent difficulty.

[6] See for instance Leftwich [7], particularly p. 246.

resulting from the piecewise linearity of the demand function facing the leader.

The necessary condition for optimal output by the leader is then

$$\alpha_0 + 2\alpha_1\xi_1 + \alpha_1\xi_2 + \alpha_1\xi_1 \frac{d\xi_2}{d\xi_1} - \gamma_1 = 0$$

or

$$\alpha_0 + \alpha_1\xi_1 + \alpha_1\xi_2 - \gamma_1 = -\alpha_1\xi_1\left(1 + \frac{d\xi_2}{d\xi_1}\right) \tag{8}$$

From (7) and (8),

$$\mu_1 = -\alpha_1\xi_1\left(1 + \frac{d\xi_2}{d\xi_1}\right)$$

and hence total profits of the leader are

$$\mu_1\xi_1 = -\alpha_1\xi_1^2\left(1 + \frac{d\xi_2}{d\xi_1}\right). \tag{9}$$

At equilibrium, we have $\gamma_2 = \Pi$ or, by (5) and (6),

$$\beta_0 + \beta_2\xi_2 = \alpha_0 + \alpha_1(\xi_1 + \xi_2). \tag{10}$$

It follows from (10) that

$$\frac{d\xi_2}{d\xi_1} = \frac{\alpha_1}{\beta_2 - \alpha_1} \tag{11}$$

and hence (9) becomes

$$\mu_1\xi_1 = -\frac{\alpha_1\beta_2}{\beta_2 - \alpha_1}\xi_1^2. \tag{12}$$

Also, by an argument similar to the one employed for the leader, total (normal) profits of the competitors are given by

$$\mu_2\xi_2 = \tfrac{1}{2}\beta_2\xi_2^2. \tag{12a}$$

Figure 1 depicts the classroom solution of the leading firm case, where AB represents the demand faced by the leader for $\Pi > \beta_0$ and AC is the marginal revenue derived from it. Algebraically, the solution is obtained by solving the system (8), (10), and (11). This yields

$$\xi_1 = \frac{\alpha_1(\beta_0 - \gamma_1) + \beta_2(\gamma_1 - \alpha_0)}{2\alpha_1\beta_2} \tag{13}$$

$$\xi_2 = \frac{\alpha_0 - \beta_0}{\beta_2 - \alpha_1} + \frac{\alpha_1}{\beta_2 - \alpha_1} \cdot \frac{\alpha_1(\beta_0 - \gamma_1) + \beta_2(\gamma_1 - \alpha_0)}{2\alpha_1\beta_2} \tag{14}$$

Note that in Figure 1 the triangles $\gamma_1 AG$ and $\beta_0 \Pi F$ represent (12) and (12a), respectively.

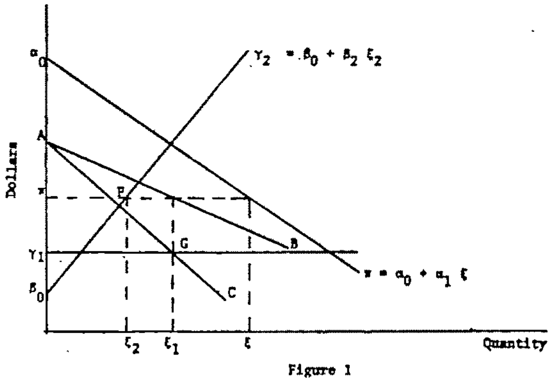

Figure 1

Turning to the programming formulation of the single commodity case, consider the problem of finding ξ_1, ξ_2 which maximize

$$[(\alpha_0 - \gamma_1)(\alpha_0 - \beta_0)]\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} + [\xi_1 \ \ \xi_2] \cdot \begin{bmatrix}\alpha_1\left(1 + \dfrac{\beta_2}{\beta_2 - \alpha_1}\right) & \alpha_1 \\ \alpha_1 & (\alpha_1 - \beta_2)\end{bmatrix}\begin{bmatrix}\xi_1\\ \xi_2\end{bmatrix} \tag{15}$$

subject to

$$\alpha_1\left(1 + \frac{\beta_2}{\beta_2 - \alpha_1}\right)\xi_1 + \alpha_1\xi_2 \leq \gamma_1 - \alpha_0 \tag{16}$$

$$\alpha_1\xi_1 + (\alpha_1 - \beta_2)\xi_2 \leq \beta_0 - \alpha_0. \tag{17}$$

The best way to interpret (15) is to break it down into its various components. These will be seen to be total revenue, total costs, and total profits.

Total revenue is given by

$$\alpha_0(\xi_1 + \xi_2) + \alpha_1\xi_1^2 + \alpha_1\xi_2^2 + 2\alpha_1\xi_1\xi_2; \tag{15a}$$

total costs by

$$\gamma_1\xi_1 + \beta_0\xi_2 + \tfrac{1}{2}\beta_2\xi_2^2; \tag{15b}$$

and, from (12) and (13), total profits are given by

$$-\alpha_1\xi_1^2\left(1 + \frac{\beta_2}{\beta_2 - \alpha_1}\right) + \frac{1}{2}\beta_2\xi_2^2. \tag{15c}$$

Subtracting (15b) and (15c) from (15a), we obtain (15).

Turning to the constraints, (16) is (8) written

in the form of an inequality with the help of (11), while (17) bears the same relation to (10). Since our problem is self-dual in the sense explained above, it follows that if ξ_1 and ξ_2 are both positive, (16) and (17) will hold as equalities and thus the program's solution will coincide with (13) and (14).

The optimal value of (15) is zero, as it should be because of the structure of (15). The interesting point is that there exists an overall function whose maximization leads to market equilibrium.

The use made of the classroom case of the leading firm was intended only to facilitate the discussion of the programming approach. We are now ready to return to the activity analysis structure and omit the assumption of linear marginal cost schedules. Moreover, henceforth we do not assume knowledge of the supply function of the competitive followers.

More specifically, it is well known from linear programming that marginal cost functions in the present context have the general form depicted by the curve $\pi_1 A$ in Figure 2. The line segments BB and CC and the ray emanating from D represent the derived demand facing the leader, while BB' and $C'C'$ depict the corresponding marginal revenue. The equilibrium solution is $(\pi^0, \xi_1^0, \xi_2^0)$.

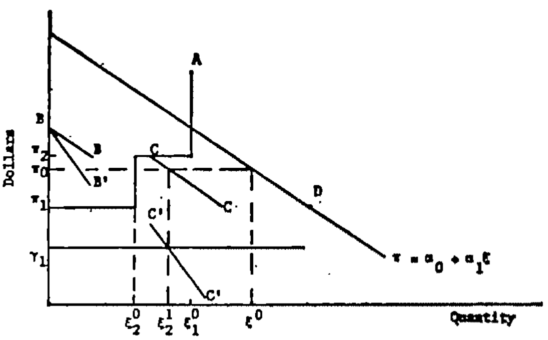

Figure 2

We observe next that the slope of BB as well as CC is α_1; that is,

$$\frac{d\pi}{d\xi_1} = \frac{d\pi}{d\xi} \tag{18}$$

for every point for which the left hand side of (18) is defined. Now, $d\xi = d\xi_1 + d\xi_2$ by definition. Hence,

$$\frac{d\xi}{d\xi_1} = 1 + \frac{d\xi_2}{d\xi_1}\,.$$

But from (18)

$$\frac{d\xi}{d\xi_1} = 1,$$

which implies

$$\frac{d\xi_2}{d\xi_1} = 0 \tag{19}$$

whenever the latter is defined.

A difficulty arises when, for instance, $\pi = \pi_2$. The problem is created by the fact that as $\pi \to \pi_2$ from below, $\xi_2 = \xi_2^0$ while as $\pi \to \pi_2$ from above, $\xi_2 = \xi_2^1$ (see Figure 2). In the programming context, a solution in which $\pi = \pi_2$ is a degenerate solution. We shall thus restrict our discussion henceforth to nondegenerate solutions. It should be noted that from now on we need not assume $\xi_2 > 0$, since all nondifferentiable points have already been ruled out by the last assumption.

Proceeding now with the aid of (19), we can replace (8) by

$$\alpha_0 + \alpha_1\xi_1 + \alpha_1\xi_2 - \gamma_1 = -\alpha_1\xi_1 \tag{20}$$

and (9) by

$$\mu_1\xi_1 = -\alpha_1\xi_1^2. \tag{21}$$

These results can now be generalized. Let $x = x^1 + x^2$, where x^1 is the output vector of the leader and x^2 that of the followers. Correspondingly, we define c^1, c^2 as costs; A^1, A^2 as technology matrices; b^1, b^2 as resource vectors; and u^1, u^2 as "shadow prices", relative to b^1 and b^2. The demand system is given by

$$p = a + D(x^1 + x^2).$$

Problem II is to find nonnegative x^i, u which maximize

$$\begin{aligned} &f_2(x^1, x^2, u^1, u^2) \\ &\quad = (a - c^1)'x^1 + (a - c^2)'x^2 + x^{1\prime}Dx^1 \\ &\qquad + x^{1\prime}Dx^2 + x^{2\prime}Dx^1 + x^{2\prime}Dx^2 \\ &\qquad - b^{1\prime}u^1 - b^{2\prime}u^2 + x^{1\prime}D'x^1, \end{aligned} \tag{22}$$

subject to

$$A^i x^i \leqq b^i \qquad i = 1, 2, \tag{23}$$

$$(D + D')x^1 + Dx^2 - A^{1\prime}u^1 \leqq c^1 - a, \tag{24}$$

$$Dx^1 + Dx^2 - A^{2\prime}u^2 \leqq c^2 - a. \tag{25}$$

In (22) the term $x^{1\prime}D'x^1$ is the equivalent of the first term of (15c);[7] (24) corresponds to (16)

[7] Except for the sign, since (15c) appears in (15) with a negative sign.

and (20); and (25) to (17). That is, $(-x^{1\prime}D'x^1)$ represents total monopolistic profits of the leading firms; (24) requires that the leaders' marginal revenue does not exceed their marginal cost; and (25) prohibits the followers' marginal cost from falling short of the price realized by them. This interpretation of $(-x^{1\prime}D'x^1)$ can be verified if one premultiplies (24) by x^1 and rearranges terms. This yields

$$(26)\quad \begin{aligned} &x^{1\prime}a + x^{1\prime}Dx^1 + x^{1\prime}Dx^2 \\ &\qquad - x^{1\prime}(c + A^{1\prime}u^1) \le - x^{1\prime}D'x^1. \end{aligned}$$

The left hand side of (26) represents profits; hence, if (26) holds as a strict equality, its right hand side must equal profits. That (26) will, in fact, hold as an equality for optimal x^1, x^2, u^1 follows from the self-duality.

It is obvious from the formulation that the only possible differences between leader and followers arise from technology and availability of resources. Technological differences are reflected in differences between $A^{i\prime}$s and $c^{i\prime}$s whereas the $b^{i\prime}$s represent differences in resources. It is therefore evident that in general we will find $u^1 \neq u^2$. This gap can serve as a measure of the losses to the economy due to monopolistic power and as a guide for taxation. It should be noted, however, that (23) could be replaced by

$$\sum_{i=1}^{2} A^i x^i \leqq b$$

in which case we would have in (22) $(-bu)$ instead of $(-b^1u^1 - b^2u^2)$; and $A^{1\prime}u^1$, $A^{2\prime}u^2$ in (24) and (25) would become A^1u' and $A^{2\prime}u$. That is to say, a noncompetitive structure of the product market does not necessarily either imply or result from a noncompetitive structure of the factor market. This is also true of the problems below.

Monopoly

The simplest case is that of pure monopoly. Problem IIIa consists of finding a nonnegative x which maximizes

$$f_3(x) = (a - c)'x + x'Dx$$

subject to

$$Ax \leqq b$$

That the solution is in fact a monopolistic one can be verified through an examination of the dual to Problem IIIa.[8]

A little more involved is the case in which only some of the goods are monopolized while others are produced under competitive conditions. Consider the partition $x' = (x^{1\prime}\ x^{2\prime})$ where the superscript "1" denotes monopolized and the superscript "2" competitive industries. This partition induces the following further partitions:

$$\begin{bmatrix} p^1 \\ p^2 \end{bmatrix} = \begin{bmatrix} a^1 \\ a^2 \end{bmatrix} + \begin{bmatrix} D^{11} & D^{12} \\ D^{21} & D^{22} \end{bmatrix} \begin{bmatrix} x^1 \\ x^2 \end{bmatrix}$$

where D^{ij} is the matrix of partial derivatives of prices of goods in group i with respect to quantities produced in group j.

Problem IIIb consists of finding nonnegative x^i, u^i, $i = 1, 2$, which maximize

$$\begin{aligned} &f_4(x^1, x^2, u^1, u^2) \\ &\quad = \sum_{i=1}^{2} \left[(a^i - c^i)'x^i + \left(\sum_{j=1}^{2} x^{i\prime} D^{ij} x^j \right) - b^{i\prime}u^i \right] \\ &\quad\quad + x^{1\prime}D^{11\prime}x^1 \end{aligned}$$

subject to

$$A^i x^i \leqq b^i, \qquad i = 1, 2$$

$$(27)\quad \begin{aligned} &\begin{bmatrix} D^{11} + D^{11\prime} & D^{12} \\ D^{21} & D^{22} \end{bmatrix} \begin{bmatrix} x^1 \\ x^2 \end{bmatrix} \\ &\qquad - \begin{bmatrix} A^{1\prime} & 0 \\ 0 & A^{2\prime} \end{bmatrix} \begin{bmatrix} u^1 \\ u^2 \end{bmatrix} \leqq \begin{bmatrix} c^1 - a^1 \\ c^2 - a^2 \end{bmatrix} \end{aligned}$$

The first constraint in (27) prescribes that marginal revenues in monopolized industries may not exceed marginal costs, while the second constraint is similar to (4). The expression $(x^1D^{11\prime}x^1)$ represents monopolistic profits (cf. [26]).

The above formulations demonstrate how the technique may be used to "imitate" those structures that we have dealt with; it may be extended to other structures, and we shall now proceed to indicate the usefulness of the proposed approach.

Application

Three of the above models were applied to the apple and pear markets in Israel. These two fruits are closely related, since they compete strongly both for the consumer's budget and for cold storage facilities. Plantations of both have undergone considerable expansion in recent years, and it is therefore probable that there will be a substantial reduction in prices, particularly of pears.

[8] This is the only problem for whose solution self-duality is not required.

The market for both fruits is currently organized along leading firm lines. The leader is a marketing cooperative that controls about 60 percent of the harvest. The remainder is marketed through a multitude of wholesalers. However, a fruit marketing board is to be established which will have legal power to dictate marketing quotas and might thus reconstruct the market along monopolistic lines.

The present situation and the anticipated changes led us to attempt to compute equilibrium prices for four possibilities: free competition; a leading firm structure; monopoly for apples only; complete monopoly. Linear "demand" functions were estimated and Problems I, II, IIIb, and IIIa were solved for this industry. It was assumed that the total yields are given, the difference between leader and followers being in the total product at the disposal of each. The results are given in Table 1.

As can be seen, the quantities of pears in Problem IIIb are not the same as in Problem I, while the prices are identical. The reason for this is that since the marginal costs are the same in both cases, so are the prices. However, since in Problem IIIb the quantity of apples is less than in Problem I, the price of 5.5 cents per pound in IIIb is reached for a greater quantity of pears than in I. The basic reason is that price cross-elasticities are negative.

One kind of information that is of interest is the loss of welfare due to monopoly. This loss was calculated for the transition from Problem I to Problem IIIa via Problem IIIb. In calculating this loss, we follow Berry [1], who has shown that the loss of welfare in terms of the sum of consumers' and producers' surplus can be extended to cases of interrelated commodities.

Table 1

Problem	Variable	Apples	Pears	Total
I	x^*	159.6	78.9	—
	p^*	12.1	5.5	—
	xp^*	19.3	4.3	23.6
II	x^1	95.8	9.5	—
	x^2	63.8	37.1	—
	x	159.6	46.6	—
	p	15.1	16.4	—
	xp	24.1	7.6	31.7
IIIb**	x	110.9	81.0	—
	p	17.4	5.5	—
	xp	19.3	4.5	23.8
IIIa	x	144.6	20.0	—
	p	19.8	24.1	—
	xp	28.6	4.8	33.4

* Quantities are in million pounds, farm prices in cents per pound, and revenues in million dollars.
** Monopoly in apples.

In these terms, the loss due to a monopoly in apples alone is approximately 1.654 million dollars while the loss from a simultaneous monopolization is about 7.932 million dollars. In addition, some 10 million dollars are passed from consumers to producers, so that the loss to consumers is, in our case, almost 18 million dollars (as marginal costs are constant, and hence producers' surplus is zero under competition). This amounts to an average loss of $6.3 per capita per year.

Our application was intended primarily as a demonstration of the models developed. It was performed under extremely simplified assumptions and should not lead to practical conclusions regarding the market under consideration. In particular, the demand estimates used here are outdated, since they were obtained before the June 1967 war. We thus hope that more elaborate studies will follow.

A Dynamic Economic Model of Pasture and Range Investments*

OSCAR R. BURT

The traditional economic replacement problem is extended to accommodate a situation where quasi-rents of future replacements are influenced by replacement age of the currently held asset. This generalized replacement model is applied to optimal timing of the clearing of brush and scrub timber from pasture and range. Dynamic programming is applied to the problem and the structure of the decision rule analyzed. An approximately optimal decision rule is deduced by an analysis of the limiting behavior of the optimal policy. An illustrative example is given for pinyon-juniper control in southwestern United States.

THE PROBLEM OF choosing optimal frequencies for long-term improvements in pasture and range is of widespread importance, extending from the arid western to the humid eastern United States. A discussion of this problem, particularly as it is exemplified by pinyon-juniper encroachment in the Southwest, is given by Cotner [9]. Brush and noncommercial timber are competitors for pasture in much of the Southeast, presenting a problem comparable to that of pinyon-juniper in the Southwest. The pasture gradually deteriorates as brush and timber cover more and more of the land area. Chemical spraying, bulldozing, burning, or other methods for destroying the brush and timber will rejuvenate the pasture and start a new cycle of first increased pasture productivity and ultimately decreased productivity caused by new brush and timber. Of course, the removal of brush and timber may be associated with other investments such as fertilization and seeding.

Optimal frequency of the renovation process poses an interesting problem in economic dynamics. In most respects it is an added complexity to the classical replacement problem [5, 10]. Within the context of replacement theory, we have a situation where replacement age of an asset influences the quasi-rent functions of assets following in the chain of replacements. The traditional replacement model assumes no such relationship among the assets that follow one another as replacements; i.e., the only argument assumed to be in the quasi-rent function is age of the asset currently held. The more complicated situation encountered in many pasture and range investments requires that the counterpart to replacement age of the currently held asset enter in the quasi-rent function of at least the immediately following replacement and possibly in succeeding replacements. Thus, we have a much more dynamic relationship than in the common replacement model.

The complex replacement problem dealt with in this article appears to be quite unique to agriculture, or at least to biological processes. Only pasture and range improvements are analyzed here, but an extension of the model would permit analysis of crop rotations. Another area for which the same basic approach could be used is in the analysis of optimal timber rotations where multiple age stands are mixed together to fully exploit available radiation, water, and other nutrients.

In an application to pinyon-juniper control in the Southwest, Cotner was apparently the only one thus far to have dealt with this extension of the ordinary replacement problem. However, his method of determining the optimal length renewal period was not very satisfactory. His stated criterion [9, p. 743] was maximization of the internal rate of return on the investment, but he contradicted this criterion by discounting benefits at fixed interest rates. Not only that; the basis of achieving his criterion was supposedly a rule given by Boulding [4] for point-input-point-output assets such as wine or timber, which are a simplified case of the classical replacement problem. There were several other simplifying assumptions in Cotner's work, but they seem relatively unimportant compared with the ambiguity of his criterion function and the "necessary" conditions used to optimize it.

We begin with a precise statement of the problem under the assumption of a first-order dependence structure in the quasi-rent func-

* Contribution from Montana Agricultural Experiment Station, Journal Series No. 247. This research was begun under the auspices of the Missouri Agricultural Experiment Station. The helpful comments of R. O. Wheeler on an earlier draft are gratefully acknowledged.

tions. Next, the problem is formulated in a dynamic programming framework and the structure of the solution examined. Then asymptotically optimal decision rules are examined and evaluated as approximately optimal decision rules in general. Higher order dependence structures in the quasi-rents are dealt with in dynamic programming formulations. Finally, an illustrative example is presented, based largely on Cotner's data for pinyon-juniper.

A Markovian Model of Pasture and Range Renewal

Renewal cycle is defined as the length of period beween two investments in pasture or range improvement, of a major type such as removal of scrub timber and brush. In the completely general case the length of the current renewal cycle affects quasi-rents in all future renewal cycles. If T_j is the length of the renewal period for the jth renewal, then T_j appears in the quasi-rent function of cycles $j+1, j+2, \ldots$ A Markovian or first-order dependence structure would limit T_j to an argument of the quasi-rent function in only cycle $j+1$. A Markovian structure is assumed for now, but it will be shown how to accommodate more general dependence structures later. If the optimal renewal cycles are relatively long, one would expect the Markovian assumption to be quite palatable, since the influence of any earlier renewals would have considerable time to dissipate.

With our assumption of Markovian dependence in the quasi-rent functions, we have two arguments in the quasi-rent function associated with a particular renewal cycle. Let u be length of the previous cycle and v the number of years since the last renewal. As u is increased, holding v constant, brush and timber deteriorate the pasture to a greater extent before their removal and thus reduce quasi-rents in the renewal cycle after their removal. Therefore, u reflects the lagged effect of encroachment and the Markovian assumption implies that the lagged effect remains for only one renewal period. Holding u constant, the quasi-rent function first increases as v is incremented from zero and ultimately a maximum is reached from which quasi-rents diminish as v increases further. The interval of increasing quasi-rents with respect to v is a consequence of the forage recovering from the adverse conditions caused by the brush and timber before its removal. The transition to decreasing quasi-rents is at the point where currently encroaching brush and timber overtake the recovery process.

We denote the quasi-rent function by $R(u, v)$, where u and v are as defined above and the cost of control equation is denoted $c(v)$. The variable, v, is essentially age of the current stand of brush and timber, while u is age of the previous stand at the time it was controlled. The quasi-rent function $R(u, v)$ is defined as the maximum net value with respect to variable factors applied to the operation. Any variables, such as stocking rate, which might interact with the rate of encroachment of brush are assumed to be fixed and are not a part of the optimization process.

When economic and biological conditions are such that pasture renewal implies complete reseeding with destruction of any old stand of forage, the lagged effect of the last renewal, reflected in the variable u, is completely wiped out. The current model then degenerates to the ordinary replacement problem, since the quasi-rent function is then merely $R(v)$. Under current technology and prices, it would appear that complete reseeding with a prepared seedbed is economic only on relatively productive sites with adequate rainfall to give a high probability of success.

The methods of control used from one renewal to another are assumed equivalent in physical performance. They need not be identical, except in their effect on the pasture or range.

Length of the renewal cycle is treated as a continuous variable, primarily for convenience of analysis, but the modifications are straightforward to restrict the cycle to integers. In fact, numerical solution of the dynamic programming equation would almost certainly be done with the integer restriction.

Straightforward specification of a present value criterion function and its differentiation with respect to length of renewal cycles yields an intractable difference equation. Therefore, we depart from classical methods and formulate the problem in a dynamic programming model from which inferences are drawn about the dynamic structure of the optimal decision rule. Then necessary conditions are derived for the optimal policy when the process has converged to its asymptotic limit.

A Dynamic Programming Formulation

The approach used here closely parallels that used by the author in analyzing replacement decisions [5], in which the stage of the multi-

stage decision process was defined by the number of replacements remaining to be made within the firm's planning horizon, in contrast to the more orthodox method of using discrete time periods to define the stage of the process [2]. In this application of dynamic programming the stage is defined by the number of pasture renewals remaining in the planning horizon. By defining stages in this way instead of in fixed time periods, the number of state variables is reduced by one under an infinite planning horizon.

We introduce the following notation:

- p = stage of the process, i.e., the number of pasture renewals yet to be made within the planning horizon
- n = number of years remaining in the planning horizon
- T = length of the renewal period associated with stage p
- m = length of the renewal period immediately preceding stage p in time, i.e., the renewal period associated with stage $p+1$
- $f_p(m, n)$ = present value of all quasi-rents from the remainder of the planning horizon; given stage p, n years remaining in the planning horizon, an immediately preceding renewal period of length m, and that an optimal policy is followed.

Application of Bellman's "principle of optimality" [1, p. 83] to the pasture renewal problem gives the recursive equation

$$f_p(m, n) = \operatorname*{Max}_T\left[\int_0^T e^{-ix}R(m, x)dx - e^{-iT}c(T) + e^{-iT}f_{p-1}(T, n-T)\right], \quad 0 \leq T \leq n. \tag{1}$$

The first state variable m is transformed into T and the second state variable n is transformed into $n-T$ by the transition from stage p to stage $p-1$. These transformations are the crux of the dynamic structure of the problem and follow directly from the definitions of m, n, and T. We have tacitly specified the initial position from which the process begins to be the beginning of a renewal cycle, but it is easily shown that this position is arbitrary and does not affect the optimal policy.

As the planning horizon becomes infinite, the second state variable can be deleted since $n-T \rightarrow n$ as $n \rightarrow \infty$ if T is finite. From a practical point of view, the case where T is not finite is of no interest because the solution would imply no pasture rejuvenation, merely the native equilibrium conditions. Assuming $R(m, x)$ and $c(T)$ are bounded functions, $i>0$, and T is bounded, we can apply a general theorem of Bellman [1, p. 121] which implies that $f_p(m, n) \rightarrow f_{p-1}(m, n)$ and the optimal policy function $T_p(m, n) \rightarrow T_{p-1}(m, n)$ as $p \rightarrow \infty$. The optimal policy function is the solution of (1) for given values of p, m, and n. We can write a simplification of (1) under the limiting case where both p and n increase without limit:

$$f(m) = \operatorname*{Max}_T\left[\int_0^T e^{-ix}R(m, x)dx - e^{-iT}c(T) + e^{-iT}f(T)\right], \quad 0 \leqq T \leqq b, \tag{2}$$

where b is an arbitrarily large but finite number. As a consequence of the convergence theorem to which we appealed in deducing (2) from (1), $f(m)$ is a continuous function if $R(m, v)$ and $c(T)$ are continuous.

Either relation (1) or (2) can be solved by numerical methods utilizing an electronic computer [3], but we are also concerned about the structure of the solution and simplified decision rules. At the expense of some well known restrictive assumptions, we can write (2) without the maximum operator and substitute an equation implied by setting the first derivative with respect to T of the expression in brackets equal to zero. Thus,

$$f(m) = \int_0^T e^{-ix}R(m, x)dx - e^{-iT}c(T) + e^{-iT}f(T), \tag{3}$$

$$R(m, T) + ic(T) - c'(T) - if(T) + f'(T) = 0[1] \tag{4}$$

are an alternative for (2) that is more amenable to further analysis. The second-order conditions for a maximum, which must hold together with the necessary conditions of (4), are

$$\partial R(m, T)/\partial T + ic'(T) - c''(T) - if'(T) + f''(T) < 0. \tag{5}$$

[1] We are using the common notation of primes to denote first partial derivatives, e.g., $g'(x) = \partial g/\partial x$.

We are particularly interested in $\partial T/\partial m$ with respect to sign and magnitude because it is the source of inferences about the dynamic behavior of the decision process. Let us return to the notation $T_1, T_2, \ldots$, where T_i is length of the ith renewal period measured with origin at the *beginning* of the planning horizon. Then $\partial T/\partial m$ is equivalent to $\partial T_i/\partial T_{i-1}$. The relationship between T_i and T_{i-1}, say $T_i=\phi(T_{i-1})$, is an implicit one; and for a given value of T_{i-1}, $\phi(T_{i-1})$ implies simultaneous solution for $T_i, T_{i+1}, \ldots$,. However, the Markovian dependence of our criterion function permits this implicit solution for $T_{i+1}, T_{i+2}, \ldots$ to be incorporated in the functional equation $f(T)$. Thus, conceptually at least, we have a first-order difference equation $T_i=\phi(T_{i-1})$ which can be analyzed in general without an explicit algebraic specification of the function ϕ.

Samuelson [11, p. 303] delineates all possible types of qualitative behavior of this function in the neighborhood of an equilibrium. If ϕ' is positive, the approach to equilibrium is asymptotic; if negative, equilibrium is approached by dampened oscillations, assuming a stable equilibrium exists. A necessary condition for stability is "stability in the small" which means movement back toward equilibrium for sufficiently small disturbances from equilibrium [11, p. 262]. Stability in the small implies $|\phi'|<1$. Going back to (3) and (4), we have evidence of stability if $|\partial T/\partial m|<1$; and the sign of $\partial T/\partial m$ indicates whether the equilibrium is approached asymptotically or through dampened oscillations.

Differentiation of (4) yields:

$$\frac{\partial T}{\partial m}=-\frac{\partial R(m,T)}{\partial m}\bigg/\left[\frac{\partial R(m,T)}{\partial T}+ic'(T)-c''(T)-if'(T)+f''(T)\right]. \tag{6}$$

The denominator of the right hand side of (6) must be negative to meet the second-order condition of (5); thus the sign of $\partial T/\partial m$ is determined by the sign of $\partial R/\partial m$. Also, (5) suggests that there will be a tendency for $|\partial T/\partial m|<1$ if $|\partial R/\partial m|$ is small relative to $|\partial R/\partial T|$. Note that we are using $\partial R/\partial m$ and $\partial R/\partial T$ to denote the partial derivatives of $R(u, v)$ at the point (m, T).

The sign of $\partial R/\partial m$ has already been established as negative because of the physical relations involved in pasture and range renewal. Therefore, *any stable equilibrium is of the oscillatory type.* The condition that $\partial R/\partial m$ be small relative to $\partial R/\partial T$ in pasture renewal implies that the immediate effect of encroaching brush and timber dominates the lagged effect of the previous stand of brush and timber. Certainly this seems plausible, and we would also expect $\partial R/\partial m$ to be near zero at $v=T$ if the lagged effect dissipates itself within one renewal period.

Differentiation of (3) with respect to m, treating T as implicitly a function of m, and assuming the second-order condition given by (5) is met, $f'(m)$ is negative since $\partial R(m, T)/\partial m<0$. Typically one would expect $c'(T)>0$. Thus the two terms in the denominator of (6) that contain the interest rate, i, are positive and increase in magnitude with respect to i. Therefore high interest rates will tend to decrease the absolute value of the denominator in (6) and constitute a force toward instability. Also, a sufficiently high interest rate would prevent relation (5) from holding.

An Asymptotic Decision Rule

As an approximately optimal decision rule we consider moving directly to the equilibrium associated with the optimal policy instead of moving toward that equilibrium by following the optimal policy. In other words, let us look at a policy that skips the transition to equilibrium and jumps the process immediately to that equilibrium. This view of the decision problem allows it to be stated in a form amenable to the calculus, and only one variable must be determined—optimal cycle length in equilibrium. The results are only of a quasi-dynamic nature, analogous to economic growth models that look only at the optimal growth path for the nation once the path is reached, without consideration of how to optimally reach that path.

Present value of quasi-rents from the pasture or range under a constant renewal cycle can be written as

$$V(m,T)=\int_0^T e^{-ix}R(m,x)dx-e^{-iT}c(T)+\frac{e^{-iT}}{1-e^{-iT}}\left[\int_0^T e^{-ix}R(T,x)dx-e^{-iT}c(T)\right], \tag{7}$$

where m is length of the immediately com-

pleted cycle and T is the cycle length to be maintained perpetually. Differentiation of (7) with respect to T, setting the derivative equal to zero and setting $m=T$, yields

$$R(T, T) + ic(T) - c'(T) + \int_0^T \frac{\partial R(T, x)}{\partial T} e^{-ix}dx = \frac{i}{1-e^{-iT}}\left[\int_0^T e^{-ix}R(T, x)dx - e^{-iT}c(T)\right]. \tag{8}$$

Setting $m=T$ puts the initial state of the process at equilibrium. In finding the necessary conditions for equilibrium the initial state must be taken as given, and the necessary conditions for maximum present value under a fixed renewal cycle are then derived. These necessary conditions are applicable for any initial state m; so when m is set equal to the implied renewal cycle, the resulting equation implies the equilibrium cycle. Putting $m=T$ in (7) before differentiation to get the counterpart of (8) would give erroneous results. Relation (8) defines T for the equilibrium to which the decision process converges when following the decision rule implied by the functional equation of the dynamic programming model—equation (2) or equations (3) and (4).

An economic interpretation of the individual terms in (8) shows the equation to be a marginal condition with considerable intuitive appeal. The first term, $R(T, T)$, is marginal immediate net returns; $ic(T)$ is interest on renewal costs; $c'(T)$ is marginal renewal costs; the integral on the left side of the equation is discounted marginal lagged effects on net returns from a complete production cycle; and the right hand side of the equation is amortized present value of the pasture operated under the optimal renewal period. The left hand side of (8) is marginal net returns associated with an increment to the renewal period, T, while the right hand side is the marginal net returns associated with immediate renewal. Direct application of (8) to determine the renewal cycle moves the decision process from any initial state directly to the equilibrium that would be approached asymptotically under an optimal policy.

As far as an approximately optimal policy is concerned, direct maximization of (7) for a given initial state m is preferable to solving for T in equation (8). Denote the solution of (8) by T^* which is the asymptotic cycle under an optimal policy. Unless the initial state is equal to T^*, choosing T to maximize (7) will provide a better policy than T^* since

$$\max_T V(m, T) \geq V(m, T^*).$$

Since only integer values of T are meaningful, a practical means of solution would be to merely tabulate $V(m, T)$ for various values of T, i.e., a direct search for the maximum. However, the necessary conditions for $V(m, T)$ a maximum for any given value of m, not necessarily equal to T, are

$$R(m, T) - e^{-iT}[R(m, T) - R(T, T)] + ic(T) - c'(T) + \int_0^T \frac{\partial R(T, x)}{\partial T} e^{-ix}dx = \frac{i}{1-e^{-iT}}\left[\int_0^T e^{-ix}R(T, x)dx - e^{-iT}c(T)\right]. \tag{9}$$

In the event that continuous functions are used in an application, solution of (9) in the variable T for given values of m yields an approximately optimal decision rule. The magnitude of m is a predetermined variable at any point in the decision process.

It should be kept in mind that the maximizing value of T for given m, determined for all m, constitutes the approximately optimal decision rule. The same renewal cycle is not repeated except when m turns out to equal the maximizing value of T. The specified constant renewal cycle is merely a means to an end, i.e., derivation of an approximately optimal decision rule. Of course, it also provides a convenient way to find the equilibrium renewal cycle as well.

If a rancher has several tracts of land that had different length renewal cycles previously, i.e., m is not the same for each tract, and the time elapsed since the last renewal is different from tract to tract, one might ask which tract should be renewed this year or which tract should be renewed first. Assuming that the discount rate, i, is in fact an exogenously determined opportunity cost of capital, either of these questions is answered by the optimal decision rule that specified an optimal T for each value of m, say $T(m)$.

It is assumed that the various tracts are of

homogeneous productivity. Let v_j be the time since renewal for the jth tract and let m_j be length of the last renewal cycle. If $v_j \geq T(m_j)$, the tract is renewed; otherwise, the rancher waits $T(m_j) - v_j$ more years before renewal.

If the discount rate, i, is not determined exogenously from the renewal policy, the present value criterion loses its validity. Under some quite specific assumptions (see [6, pp. 338–41]) the internal rate of return is applicable. The assumptions and arguments in [6] must be generalized considerably to fit the present more complex problem.

Higher-Order Dependence Structures

Let us now briefly examine the implications of a higher-order dependence structure among renewal cycles with respect to the quasi-rent functions. A second-order dependence would imply an additional argument in the quasi-rent function, $R(m_2, m_1, v)$, where m_1 is length of the last renewal period and m_2 is length of the renewal period before that, while v is the number of years since a renewal. The new variable is m_2, and m_1 is the same as m in the first-order relation.

The dynamic programming functional equation comparable to (2) is

$$f(m_2, m_1) = \underset{T}{\text{Max}} \left[\int_0^T e^{-ix} R(m_2, m_1, x)\,dx - e^{-iT} c(T) + e^{-iT} f(m_1, T) \right]. \tag{10}$$

The transformations of state variables in going from the left-hand side of (10) to the right are $m_2 \rightarrow m_1$ and $m_1 \rightarrow T$. The model and method of solution are essentially the same as before, but the burden of numerical solution is much greater [3].

If the dependence structure is too complicated to be handled by a second-order dependence model, there is an alternative formulation that requires only one state variable. Of course, it could also be used for the simpler first- and second-order cases as well, but the empirical measures required might be more difficult to estimate.

The single-state variable that replaces m_1, m_2, as well as additional renewal cycles if relevant, is an index of current range conditions. This index could be as simple a measure as the percent of land area covered by productive vegetation (or its inverse—percent of area not covered by productive species). The main influence of encroaching brush and timber that takes considerable time to dissipate is its smothering effect on the forage species. Without reseeding in a prepared seedbed, the forage plants must spread over the empty space left after removal of the brush and scrub timber. Reseeding with minimal or no seedbed preparation only expedites the recovery process, as would fertilization.

One of the most difficult empirical measurement problems is to obtain an estimate of the transformation function associated with the range index used as a state variable. Let the index be denoted by y, while the time since a renewal has been made is still denoted by v. Conceptually there exists a transformation function, say $\psi(y, v)$, which is the index associated with the following renewal cycle when y and v are the variables with respect to the current cycle. If we had an estimate of the transformation function and the quasi-rent function, $R(y, v)$, the dynamic programming functional equation would be

$$f(y) = \underset{T}{\text{Max}} \left[\int_0^T e^{-ix} R(y, x)\,dx - e^{-iT} c(T) + e^{-iT} f(\psi(y, T)) \right], \tag{11}$$

which could be easily solved by numerical methods.

If there is significant stochastic variation in the transformation of the state variable from stage to stage, an estimate of the probability distribution would permit a stochastic version of the functional equation in (11) where $f(\psi(y, T))$ is prefixed with the expectation operator. Numerical solution could be achieved by approximating the continuous variable model in a discrete Markov chain dynamic programming model such as that used by the author in [7, 8].

Conceptually at least, there is no difficulty in defining the state variable, y, as a vector that would permit more accurate description of the state of the process and thus use additional information to attain a more nearly optimal decision rule. However, numerical solution would become difficult if the vector y were to contain more than two components.

A generalization of the model to permit the quasi-rent function to reflect additional decision variables of a dynamic character would involve the calculus of variations. Introduction of stock-

ing rates into the model as a variable is an example, since quasi-rents would be a function of the stocking rate and its first derivative with respect to time. One could reformulate the dynamic programming model with the stage defined by a fixed time period instead of the renewal cycle and accommodate this generalized problem, but it would require an additional state variable that would measure stocking rate.

An Illustrative Example

This example is based on data from [9] for pinyon-juniper control in Arizona. One can hardly call it an empirical application because certain data that were not available, but required to estimate a production function, were largely fabricated. Except for these few data points, the example is an application to pinyon-juniper control. Even if these data points were experimental observations, the total number of data points would be so few that the results could be considered only suggestive.

The production function for forage is denoted $Q(u, v)$, where u is length of the preceding renewal cycle and v is time since the last renewal. Data from Cotner [9] were used as a source of data points to estimate $Q(u, v)$ but some adjustments and interpretation were required. It was assumed that the data in his Table 2 [9, p. 735] implied a condition in which new growth pinyon-juniper was continuously removed to allow the forage to reach its maximum potential productivity. It was also assumed that the previous renewal cycle was relatively long, 78 years to be exact. To adjust those data to correspond to a situation in which new growth was not continuously removed after control, it was assumed that production was as given in Cotner's Table 2 until 8 years after control but declined thereafter in relation to the percentages given in his Table 1 [9, p. 734].

The initial yield in Cotner's Table 1 is supposedly maximum potential yield after continuous control of new growth pinyon-juniper during the recovery period. We arbitrarily took the yields given in that table as $Q(0, v)$, $v=0$, 13, 26, . . . 78. The final set of data points is given in Table 1 of this paper for Cotner's medium potential site. Only two levels are available for the first variable, u, which makes any equation fitted to the data very crude with respect to the influence of that variable.

The following algebraic equation was fitted to the data of Table 1 by nonlinear least squares:

Table 1. Data points used to fit $Q(u, v)$

Previous renewal cycle, u	Time since renewal, v	Production (lbs. forage) $Q(u, v)$
0	0	464
0	13	436
0	26	310
0	39	186
0	52	135
0	65	116
0	78	97[a]
78	2	116
78	4	227
78	6	348
78	8	404
78	13	380
78	26	271
78	39	162
78	52	117
78	65	101
78	78	85

[a] Printed as 87 in [9, p. 734], but apparently a misprint when compared to the percentage of potential yield.

$$(12) \quad Q(u, v) = b_1 + b_2[e^{-b_3u-b_4v} - b_7e^{b_5u-b_6v}].$$

The seven parameters are assumed positive, which gives the function $Q(u, v)$ its desired properties on a priori grounds. First, $\partial Q/\partial u<0$ for all positive values of u and v; also, $\partial Q/\partial v$ is positive over part of its range and negative over part of it. The positive range of $\partial Q/\partial v$ is the recovery period after control, while the negative range is the encroachment period after maximum production has been reached. This production function has an asymptotic yield equal to b_1, with respect to v, for any finite value of the first argument, u. The fitted relation gave the parameter estimates in Table 2.

In this limited experience of using (12) as an algebraic form to approximate forage yield, its main defect appeared to be in the interval on v near zero when the concomitant value of u is relatively large. In particular, the function is

Table 2. Fitted production function

Parameter	Least squares estimate	Approximate standard error
b_1	68	18
b_2	[illegible]725	89
b_3	.00112	.00093
b_4	.04576	.0078
b_5	.01276	.0030
b_6	.22416	.040
b_7	.45441	.089

Standard error of the estimate: 17.6

Degrees of freedom: 10

Table 3. Renewal cost data

Years since renewal	5	10	20	30	40	50	60	70	80
Cost (dollars per acre)	0.26	0.28	0.36	0.97	1.49	2.20	2.25	2.34	2.47

negative on part of the interval, zero to unity, if u is greater than about 60. Introduction of an artificial data point with $v=0$ and $u=78$ caused a poor fit by nonlinear least squares to the entire data set. It was concluded that equation (12) is not an acceptable approximation to the production function within one or two units of zero in the second argument, v, when the first argument, u, is relatively large.

This limitation of (12) as an empirical production function is not serious, since quasi-rents will usually be zero during the renewal activity; and if deferred grazing is practiced to speed the recovery process, quasi-rents will be zero for another year or two after renewal. Therefore, the integrals involving the quasi-rents would merely have a lower limit greater than zero, two or three for example; and the production function would not be fitted to data points near zero in the second argument when the first argument is relatively large.

The following analysis of this illustrative example ignores the difficulty and integrates from zero. The resulting optimal policy implies renewal cycles of quite short duration, so no serious error is encountered, although it would be more realistic to assume some zero quasi-rents immediately after renewal.

Costs of renewal (pinyon-juniper control) were developed from Cotner's Table 3 [9, p. 737]. For a given age of stand, our variable v, it was assumed that the least-cost method would be used. This assumption implied hand chopping for $v=5, 10, 20, 30$; individual tree burning for $v=40$; and cabling for $v=50, 60, 70, 80$. Since cabling would not be comparable to other methods in completeness of control, an additional dollar per acre for supplementary hand chopping was added to costs of cabling. The resulting data points were those given in Table 3 above. The transition to cabling suggested a discontinuity in the cost function, so two separate quadratic equations were fitted, one each for v from 5 to 40 and 50 to 80. The two fitted equations were

$$(13) \quad c(v) = .30 - .01557v + .001153v^2 \qquad 0 \leq v \leq 45$$

$$(14) \quad c(v) = 2.55 - .01700v + .00020v^2 \qquad v > 45.$$

A forage value of 7 dollars per ton and an interest rate of 10 percent were assumed initially. Equation (2) was solved numerically for integer values of m and T from 5 to 75. The lower limit was imposed because the Markovian assumption could hardly hold for values of m less than 5 and the upper limit reflects the limit of the data set used. The decision rule is given in Table 4. Recall the conditional nature of the decision rule, an optimal T for each m, say $T(m)$.

Table 4. The optimal decision rule

Previous renewal cycle, m	5 to 8	9 to 13	14 to 16	17 to 75
Optimal current cycle, $T(m)$	9	8	7	5

From Table 4, it is apparent that a stable equilibrium exists between 8 and 9 years, since an equilbrium implies $T(m)=m$ and the equilibrium is approached from any initial position on the interval 5 to 75. However, the integer restriction in practice implies ultimate oscillation between 8 and 9 instead of an equilibrium. Solution of equation (8) confirmed the continuous variable equilibrium to be 8.485 years.

In order to illustrate the dynamic decision rule, assume an initial situation in which the last renewal cycle was 50 years and the time since that renewal is 25 years, i.e., $m=50$ and $v=25$. Since $v>T(m)$, the range is immediately renewed; in fact, it should have been done 20 years ago at $v=T(m)=5$ (see Table 4, last column). After the renewal, the decision process is in a new state, viz., $m=25$; and we see from Table 4 that the next renewal should be made in 5 years. After 5 years the renewal is made, and the new state is $m=5$. By Table 4, the next renewal should be in 9 years. From that renewal into perpetuity, the renewals oscillate between 8 and 9 years.

Some sensitivity analysis was performed by letting the interest rate range from 5 to 20 percent and the forage price range from 1 to 10

dollars per ton. At a forage price of 7 dollars per ton, the equilibrium was 7.82 and 9.88 years at interest rates of 5 and 20 percent, respectively. At an interest rate of 10 percent, the equilibrium was 12.62 and 8.15 years at forage prices of 1 and 10 dollars per ton, respectively. The equilibrium renewal cycle appears to be quite stable in this example with respect to either the interest rate or price of forage.

Nevertheless, a case was encountered in which an equilibrium was nonexistent, namely, at an interest rate of 20 percent and a forage price of 1 dollar per ton. Equation (8) had no solution and the solution of (2) yielded a policy as follows: $T(m)=75$, $m=5, 6, \cdots 64$, and $T(m)=5$, $m=65, 66, \cdots 75$. Thus, the optimal policy is to oscillate between the boundaries placed on the variables.

Sensitivity to costs was checked by doubling costs, which changed the equilibrium by less than one year.

The approximately optimal policy associated with maximization of $V(m,T)$ with respect to T for all values of m in equation (7) is presented in Table 5. Price of forage is 7 dollars per ton and the interest rate is 10 percent, so that Tables 4 and 5 can be compared. The policies are identical for $m=5, 6, \cdots 13$, and the remaining differences are trivial in their consequences on the criterion function.

Results of numerical problems can be only suggestive, but the results here certainly do not discourage using the approximately optimal policy. However, the computations on a digital computer are relatively simple for solution of equation (2), which may encourage derivation of the optimal policy. FORTRAN programs are available from the author to solve either problem.

Table 5. Approximately optimal policy

Previous renewal cycle, m	5 to 8	9 to 20	21 to 30	31 to 37	38 to 75
Approx. Optimal current cycle, $T(m)$	9	8	7	6	5

Resource Investments, Impact Distribution, and Evaluation Concepts*

ROBERT J. KALTER AND THOMAS H. STEVENS

Governmental decisions on proposed resource investments have always been made within an implicit multidimensional social welfare function framework. Yet the equity consequences of public programs have never been evaluated on an equal basis with their contribution to national economic growth. A model designed to facilitate the measurement of such consequences is specified and applied to a case study. The model can be used in conjunction with different equity classifications, but the test considered the personal income distribution consequences of a proposed water resource investment. The distribution of efficiency benefits and positive intergroup transfers as well as cost and reimbursement questions are considered.

EVALUATION of alternative proposals for governmental resource investment has normally not been carried out within a multiobjective framework. The single-valued objective function of national economic efficiency has been the mainstay of governmental analysis. Although Senate Document 97 gives official recognition to several other objectives, little effort has gone into perfecting the methodology necessary to obtain quantitative estimates of project effects on those objectives or of properly associating the results of such estimates with the planning process [31, pp. 16–25; 25]. Even though largely neglected by the economics profession, however, equity impacts[1] of public proposals have important implications for governmental decision making.[2] The political process can effectively utilize information on such impacts to point up and permit the resolution of decision-making bottlenecks. The result can be a smoother operating and more responsive public sector [6, p. 4].

To the extent that investment evaluation has utilized objectives other than national economic efficiency, regional development has been the primary concern [9, 15, 19]. In practice, this has led to a resurrection of the so-called secondary impact concept. Although the literature is replete with discussions of this notion [1, pp. 17–28; 2; 3, ch. 7; 5; 8; 14; 16, ch. 9; 28, pp. 8–10; 31], the term has always been conceptually ambiguous. It is widely used as a euphemism for impacts of water resource projects that are interregional transfers [19]. On the other hand, "changes in the production possibility surface of the private sector" resulting from resource investments are often referred to as secondary benefits [10]. Thus, no clear conceptual separation is provided between those effects properly considered under both national economic efficiency and distributional objectives and those of a purely distributional nature. By lumping impacts having a mixed character with respect to objectives under one classification, empirical analysis is inhibited and research results made less meaningful.

For example, evaluation of equity-distributional effects has concentrated on positive interregional transfers and the development of regional multipliers by which they can be measured. Little emphasis has been placed on questions relating to the incidence of the *various* national economic efficiency components[3] or to adverse transfers. All the appropriate components of the national efficiency impact plus the

* The assistance of Leonard A. Shabman and the comments of David J. Allee, Daniel W. Bromley, and David Seckler are gratefully acknowledged.

[1] In the study of welfare economics departures from the criterion of economic efficiency for program evaluation reduce to questions relating to the distribution of program impacts [12, p. 18; 32, p. 177]. Other issues, such as the classification of impact groups, the relevant distributional criteria, and the definition of impacts and their measurement, can all logically be placed under this framework. For example, the relevant group classification may involve regions, income groups, economic sectors, or other population segments, but all are merely different subdivisions for purposes of analyzing the distributional issue.

[2] In a broader context this applies to all public investment decisions, whether or not they are primarily for developmental purposes as defined by Leven [10], as well as to changes in public rules or institutions [21].

[3] Because transfer effects normally have not been and should not be recognized as a gain in real national income [25, pp. 5–6; 16, ch. 9; 3, ch. 7], program impacts from the national economic efficiency perspective are often said to include only the value of additional program output (valued in light of without project demand conditions) [10, 19]. However, the value of technological externalities and productivity changes caused by public investment, which are not merely transfers, should also be considered as a national effect even though they are less susceptible to quantification.

ROBERT J. KALTER *is assistant professor of resource economics at Cornell University. Thomas H. Stevens is a graduate assistant in resource economics at Cornell University.*

relevant intergroup transfer effects on the classification under consideration, however, need to be considered. Conceptually, transfers are only one component of a project's distributional consequences, since all economic efficiency impacts have distributional implications.

Several points flow from this short review. First, more emphasis is needed on empirical methods of measuring productivity changes and technological externalities resulting from public investments, and of identifying regional gainers and losers from a more comprehensive perspective than mere interregional transfers. This would serve to place in its proper perspective the now conventional approach to distributional evaluation of measuring transfer (secondary) impacts through regional multiplier analysis, as exemplified by economic base studies, regional interindustry models, and simple Keynesian models. Second, although analysts have largely neglected distribution issues of all varieties, emphasis on regions and growth in regional income has resulted in the lack of analysis of project impacts to other income groups and economic sectors, both nationally and regionally. Without such information the question of which groups and sectors gain and which lose from program implementation and whether such impacts are commensurate with society's views on equity or with the impacts of other programs cannot be fully answered.

Finally, analysis of relevant distributional impacts raises issues beyond those of impact class definition or techniques to quantify appropriate project effects. Since any project-induced change involves distributional considerations, a framework for equity evaluation is needed. Such a framework needs to consider not only the distribution of efficiency benefits and positive intergroup transfers but also cost and reimbursement[4] questions for each distributional class. A potential framework for such an analysis is the principal topic of this paper. The model presented in the next section is general in nature in that it does not attempt to identify meaningful distributional classifications [32] and assumes that measurement techniques are available to quantify all appropriate project impacts. An example of the model's application to a proposed project follows as an illustration of data requirements and empirical problems.

An Equity Evaluation Framework

Income distribution is changed by federal resource investments whenever the distribution of project *net* benefits is nonproportional to the income distribution projected to occur without the project in question.[5] Net benefits generally consist of income in kind, in that provision of public goods at a price below willingness to pay releases private resources for other uses. In order to determine the magnitude of benefits and costs accruing to a distributional classification, the benefits received are defined as a portion of total project benefits.[6] The costs borne by each classification are defined to include a portion of the indirect payment, via taxation, of total investment and operating costs of the project, and any direct payments for benefits received.[7] Then the total cost can be netted against total benefits for each classification, and the resulting net benefit distribution can be compared to a reference income distribution.

If the benefits to a distributional class accrue to that classification in the absence of reimbursement, the conceptual model is similar to that used for a national economic efficiency analysis. Therefore, the following formulation can be utilized:

[4] The term "reimbursement" refers to the partial or total repayment of project costs or, alternatively, payment for benefits received as a result of a project. In effect, reimbursements are also transfers, but they have not been adequately considered in most equity evaluations.

[5] Schmid has suggested that redistribution occurs whenever the distribution of *gross* benefits is nonproportional to the distribution of project costs [21]. This ignores, however, the fact that costs may not be distributed in proportion to reference income or assumes that society's interest in equity corresponds to the benefit principle of taxation. Schmid's formulation eliminates the need to define a reference distribution but provides little basis by which alternatives can be compared. The formulation suggested above assumes that an appropriate reference base can be defined which would be of assistance to public decision makers in comparing alternative projects and programs.

[6] For example, if the analysis takes a national viewpoint, total project benefits would correspond to national efficiency benefits. A regional analysis, however, would consider the total regional benefit of a project, including the appropriate positive transfers and national costs that benefit the region.

[7] If the *relative* impact of a project on income distribution is of major concern, reimbursement is not a complicating factor and the budget constraint is fixed, the cost side of the distribution account will be fixed and will not affect the net. Thus, only the distribution of benefits is required. If, however, the *absolute* impacts are of concern, reimbursement is required, and/or the budget constraint is flexible and depends on project evaluation, the cost side of the account must be quantified.

$$\text{Net Benefit}_a = \sum_{t=1}^{T} \frac{B_{at}}{(1+i)^t} - \left[Z_a + \sum_{t=1}^{T} \frac{O_{at}}{(1+i)^t}\right] \tag{1}$$

It is assumed that distributional classifications will not be indifferent to the timing of benefit impacts. Therefore, because benefits and costs accrue to various classifications over time, a discounting procedure is necessary to place them on a present value basis. The present value of benefits to class a is represented by the first component of equation (1). Thus, B_{at} represents the annual dollar benefit to the class, i the discount rate, and T the time horizon. The value representing benefits per unit of time can be looked upon as incorporating all relevant benefits to the distributional class under consideration. Thus, both national economic efficiency benefits, including primary impacts, externalities, and productivity effects, and the appropriate transfers would be included in this value. The second part of equation (1) specifies the total present value cost of a project to class a where Z_a represents the portion of the tax payment by class a that is allocated to the construction of the project and O_{at} represents annual operating, maintenance, and repair costs to class a. Taken as a whole, then, equation (1) represents the present value of the net benefit accruing to class a.

If reimbursement is a requirement of the project for all or a portion of its costs, however, the analysis is altered although the basic conceptual framework remains intact. Reimbursement procedures will usually have inherent distribution effects. For example, a portion of a project's investment cost may be allocated to its water supply function. Localities receiving the water supply are required, by statute, to repay over time the allocated cost of water supply. The effect of such a reimbursement procedure upon distributional groups can be seen in Table 1.

Table 1. Example of reimbursement distribution effect

Distributional class (j)[d]	Z[a]	B[b]	R[c]
c	10	20	30
d	20	30	20
e	30	20	10

[a] Z = tax revenue used to finance the water supply function by the federal government.
[b] B = benefits.
[c] R = reimbursement.
[d] J = distributional classes ($j = c, d, e$).

Table 1 assumes that class c pays 10 in taxes to finance the water supply component of the project and through consumption receives 20 in benefits (income in kind). However, federal law requires that the total investment cost of water supply (assume that all figures are on a present value basis) be repaid to the federal government by the locality receiving the supply.[8] The *initial* effect on class c is that it pays 10 in taxes and receives a benefit of 20 or a positive net benefit of 10. Assume, however, that when reimbursement is taken into consideration, the *final* effect is that class c pays 30 and receives a benefit of 20. For class c the income distribution effect changes from $+10$ to -10 because of reimbursement.[9]

If reimbursement was 100 percent and proportional to the taxes paid, distributional class c would reimburse 10/60 of total reimbursement, or 10. Proportional reimbursement may be represented as

$$P_c = \left| K_c \sum_{t=1}^{T} \frac{\left(\sum_{j=c}^{e} R_{jt}\right)}{(1+i)^t} \right| \tag{2}$$

where K_c is the proportion of the total tax paid by group c. The remainder of the expression is the present value of the total reimbursement, or 60 in the example. The proportion K_c multiplied by the present value of the total reimbursement is the amount of reimbursement that would be paid by class c if reimbursement were proportional to the appropriate tax structure.[10]

The *actual* present value of the reimbursement paid by class c may be written as

$$A_c = \sum_{t=1}^{T} \frac{R_{ct}}{(1+i)^t} \tag{3}$$

[8] The example and subsequent formulation assumes that annual operating and maintenance costs will either be paid *directly* by the project beneficiaries or will be nonreimbursable. In any case the analysis would be the same.

[9] The reimbursement figure does not include the original taxes of 10 because it is assumed that the 60 in taxes for the project was a loan by society to itself and that loan is being repaid. Therefore, although the federal tax cost to society as a whole is zero, the distribution impact is dependent on the nature of reimbursement.

[10] Note that reimbursement does not need to be 100 percent for this expression to hold.

The difference between the actual reimbursement and proportional reimbursement may be titled the "reimbursement adjustment." It is measured as a positive or negative deviation from the tax structure. The investment cost for a distributional group, therefore, consists of the initial tax plus the reimbursement adjustment. The total cost to group c is expressed by the actual investment cost plus the present value of operating and maintenance costs accruing to it. Therefore, the net benefit[11] of *any* distributional group, j, is expressed as:

$$\text{Net Benefit}_j = \sum_{t=1}^{T} \frac{B_{jt}}{(1+i)^t} - \left[Z_j + \left\{ \sum_{t=1}^{T} \frac{R_{jt}}{(1+i)^t} - K_j \left[\sum_{t=1}^{T} \frac{\left(\sum_{j=1}^{J} R_{jt} \right)}{(1+i)^t} \right] \right\} + \sum_{t=1}^{T} \frac{0_{jt}}{(1+i)^t} \right] \quad (4)$$

where $j = 1,2,3, \cdots, J$.

Implementation of the formulation for all distributional classes in the model permits calculation of both the absolute and relative distribution of net present value benefits to the classes. The relative distribution of project net benefits can then be compared with the expected distribution of income without the project to ascertain whether the project will cause an alteration in that situation.[12]

The model presented contains several simplifying assumptions for purposes of exposition. First, it assumes that the round-by-round impacts on the economy of an initial change in distribution caused by a project are of no consequence. However, the final effect of an initial change in distribution will probably differ from the initial impact measured by the model. For example, assume that an initial change in income distribution is caused by the project so that group B gains relative to group A. The expenditure patterns of group A may differ from those of group B. When group A spends any resources released because of the project, there will be other distributional effects due to that expenditure. Similarly, group B contracts expenditures, and this is felt throughout the economy. Although the model can be implemented without considering such impacts, it must be recognized that they *may* be of importance and cannot be passed off as pecuniary effects as in an economic efficiency analysis.

Second, the composition of distributional classes may change over time because of external factors; therefore, the demand by any one class for a project's output may be expected to change. Hence, the quantity consumed will be altered; and this in turn results in an altered distributional effect. Methods of handling this problem must be explored.

Finally, the actual allocation of project costs and benefits to distributional classes presents numerous empirical problems. Such allocations must, by necessity, proceed along the functional lines of the project. This is necessary because benefits arising from various functions may be distributed differently to distributional classes. Also, cost distributions can change because of reimbursement policy. Therefore, the

---

[11] If the assumption of equal marginal utility of income for all individuals or groups is considered too restrictive and if welfare equivalent weights (θj's) are available, the results of the formulation can be multiplied by the appropriate constant to obtain an improved measure of welfare change. It has been suggested that measures of income utility to different classes could be deduced from "the effective marginal rates of the personal income tax at different income levels" [4, pp. 133–34]. Such an approach uses, of course, "governmentally imposed" utilities to measure satisfaction from government expenditure.

[12] It should be noted that the income distribution effects of public investments can vary depending upon the region defined for quantification of such impacts. The model outlined above was formulated from the national point of view. To use it in a regional context, reimbursement would need to be zero or a modification of equation (4) would be needed. Such a need stems from the normal reimbursement situation in which a local or regional unit of government is required to repay to the federal government all or part of total federal costs rather than just the regional share of federal taxes devoted to a project. Thus, Z_j in equation (4), which in the regional context would denote the regional portion of federal taxes paid by income class j, would give the improper value against which the "reimbursement adjustment" should be applied. The value that should be substituted for Z_j in equation (4) can be represented by

$$Z_{j\lambda} = \alpha_{j\lambda}(\gamma Z_{jn}) + \phi Z_{jn} \quad (5)$$

where, Z_{jn} represents total federal investment cost distributed nationally to distributional classes in proportion to total federal taxes paid; $\alpha_{j\lambda}$ represents the percent of federal tax revenue paid by class j and raised in the region; γ represents the percent of nonreimbursable federal tax cost; and ϕ represents the percent of reimbursable federal tax cost. $Z_{j\lambda}$, then, represents the present value investment cost of the project borne by the regional component of class j if that cost is distributed in proportion to the federal tax structure. In other words, Z_λ is the total cost, due to both taxes and reimbursement (but without double counting), of a project to a region. The formula assumes that reimbursement will not exceed federal tax cost on a present value basis.

estimation of a project's equity impact is dependent on the method of allocation used for joint project costs (when they exist *and* when nonproportional reimbursement occurs).[13] The principal problem, in addition to the issues raised above, in allocating costs and benefits to the various distributional classes is the lack of available data by which such allocations can be made.

Thus, the model posed serves to point out the issues that have policy implications and need further research effort. First, it is clear that empirical implementation would be difficult. Little previous attention has been paid to the distribution of national economic efficiency benefits to various classes, however defined. This deficiency is important not only because of the distributional effect of such benefits but because their magnitude and incidence serve as the origin of additional transfer or multiplier impacts. Second, the model clearly points up the fact that cost sharing and reimbursement arrangements are an important means of affecting the distribution of project impacts. Not only must they be considered in the evaluation of such impacts, but they appear to be a potentially important policy tool for use by decision makers. In essence, they provide another alternative in project formulation. However, the inflexibility of current reimbursement formulas makes their utilization difficult in such a context.

Model Implementation

To illustrate empirical difficulties and to explore potential data sources, the equity model was utilized to evaluate the personal income distribution aspect of the proposed multipurpose Stonewall Jackson Reservoir in West Virginia [26]. The original economic evaluation of that proposal [24] was revised by using a $4\frac{7}{8}$ percent rather than the original $3\frac{1}{4}$ percent discount rate, and by following recently proposed guidelines [31] for estimation of efficiency benefits (see [7, pp. 8–32]). Upon reevaluation the proposal produced a 0.75 benefit-cost ratio on $35,936,000 of initial investment.

The equity model was implemented for a region surrounding the actual project site and associated downstream locations, defined by zip code areas 263 and 264. The advantage of such a definition was that all flood control and water supply benefits of the project and a majority of the recreation impacts accrue to this region. Moreover, in view of the local impact of reimbursement requirements, the absolute bulk of any distributional impact will fall in such a region. Any change in relative impact caused by taking a national rather than regional perspective would be small. Zip code areas were used to define regional lines because of available data on the present distribution of income.

Reference distribution

Adjusted gross income for 1966 as obtained from the region's federal tax returns [30] was utilized to define the present distribution of personal income.[14] This classification was used as the reference point for the study. Data limitations permitted only three income classes to be defined (Table 2).

Table 2. Reference income distribution for zip code area 263–264

Class	Percent of population in class	Percent of adjusted gross income in class
Less than $3,000	26	11
$3,000–$10,000	63	62
Over $10,000	11	27

Source: [30].

Benefit-cost allocation

As indicated, to determine the net present value of distributional effects by classes, the project's benefits and costs must be allocated to each of its primary functions. Table 3 shows the results of this allocation as determined by using the separable cost-remaining benefit al-

[13] Analytical results should not be affected by this fact as long as evaluation is consistent with and utilizes the same approach as that used for *actual* allocation of joint costs. Thus, because actual reimbursement requirements are based on the "separable cost-remaining benefit" method and because only reimbursement will alter the allocation of costs to distributional groups, the method of joint cost allocation should not affect analytical results if the model utilizes the same approach for joint cost allocation.

[14] Since the analysis was carried out using *household* income as the income base, it was assumed that the tax returns represented household income. However, such an estimate has a downward bias because of the use of separate returns within households. Data to make the necessary adjustments or improved sources of information were not available.

Table 3. Benefits and costs by project function—Stonewall Jackson Reservoir

Function	Average annual benefit	Investment cost	Average annual operating and maintenance cost[a]
	dollars		
Flood control	765,000	29,108,200	69,300
Water supply	191,900	1,796,800	−7,600
Recreation	479,000	5,521,000	102,000

[a] Negative costs arise from the nature of the separable cost-remaining benefit method when used with an economically inefficient project. In essence, one function is subsidizing another.

Table 4. Allocation of federal tax to national income groups, 1966

Class	Average federal tax per family[a]	Households in nation	Total tax in nation	Percent of federal tax paid by income class
	(1)	(2)	(3)	(4)
	dollars			*percent*
Less than $3,000	264	11,293,320	2,981,436,480	2
$3,000–$10,000	1,317	32,717,160	43,088,499,720	33
Over $10,000	5,637	14,951,310	84,280,534,470	65

[a] Average federal tax per family excludes social insurance since it is not part of revenue from which investment funds are drawn.
Source: Column (1): [23, Tables B-8 and B-9, pp. 47–48]. Column (2): [30, *Zip code area data*, 1]. Total exemptions in each income class divided by 3.29 people per household. Assumes that household and family definitions are identical.

location procedure (see footnote 13) and revised cost estimates [7]. Subsequent present value calculations utilized the currently defined government discount rate of $4\frac{5}{8}$ percent and a 100-year time horizon, except for the reimbursement portion of equation (4) where the time horizon was shortened to 50 years in accordance with the appropriate statutes [20].

Investment costs by income class.—The regional orientation of the study required the investment costs of each function to be allocated to the various income classes in accordance with equation (5). Since the federal tax costs, Z_N, of each function (or more generally of the total project) are raised from general federal revenues, they can be allocated to national income classes on the basis of an allocation of federal taxes to income classes. A recent allocation of the federal tax burden by income classes, published by the Tax Foundation in 1967, was utilized for this purpose [23]. The percentage of federal taxes allocated to the income groups defined for this study is presented in Table 4.[15]

The investment cost of each project function assigned to each income class was determined by multiplying the percentages from Table 4 by the appropriate investment costs. This calculation resulted in the distribution of *total* investment cost (Z_N). However, it is the distribution of regional costs that is desired, so the portion of total investment cost borne by the region must be determined (Table 5). For flood control, ϕ in equation (5) is equal to zero and therefore γ is equal to 100 percent. Thus, if $\alpha_{J\lambda}$ is known, the investment cost borne by each income class in the region ($Z_{J\lambda}$) for flood control can be derived. The $\alpha_{J\lambda}$ values were determined by calculating the amount of total federal income taxes paid by the respective regional income classes as a percent of total federal income taxes paid by the corresponding national classes.[16]

Table 5. Allocation of investment costs by function and income class

Class	Function	Investment cost borne by nation (Z_{JN})	Investment cost borne by region ($Z_{J\lambda}$)
		dollars	
Less than $3,000	Flood control	582,164	408
$3,000–$10,000		9,605,706	6,724
Over $10,000		18,920,330	5,676
Less than $3,000	Water supply	35,936	35,936
$3,000–$10,000		592,944	592,944
Over $10,000		1,167,920	1,167,920
Less than $3,000	Recreation	110,420	28,357
$3,000–$10,000		1,821,930	467,898
Over $10,000		3,588,650	920,551

Source: Tables 3 and 4.

Although the investment costs for water supply are initially paid from federal revenue,

[15] Several problems arise from the use of this procedure. For example, the income base is defined differently in the Tax Foundation study than by the data utilized in this study [30]. However, the difference was not expected to substantially bias the quantitative results. Another problem is that the average federal tax per family in Table 4 is based on 1960 data while the numbers of households in the nation are based on 1966 data. Therefore, it was assumed that the tax structure was unchanged from 1960 to 1966.

[16] The percentages were .07 percent, .07 percent, and .03 percent for the under $3,000, $3,000–10,000, and over $10,000 classes, respectively [26].

the Federal Water Supply Act stipulates that 100 percent of the total investment cost must be repaid to the Federal Government with interest at 4⅞ percent on the unpaid balance over a 50-year period. Therefore, ϕ is equal to 100 percent and $Z_{J\lambda}$ is equal to the investment cost for the function times the percent of federal taxes paid by the appropriate national income class (Table 4). This provides the cost of investment to the regional income classes when reimbursement is proportional to the federal tax structure.

The Federal Recreation Act stipulated that 50 percent of the *separable investment cost* of recreation be repaid to the Federal Government with interest at 4⅞ percent on the unpaid balance over a 50-year period. Thus, ϕ is equal to 25.6 percent and γ to 74.4 percent based on separable costs of $1,415,000 and total costs of $5,521,000. Using the appropriate Z_{JN} and $\alpha_{J\lambda}$ values gave the results shown in Table 5.

Benefits and annual costs by income class.— Data concerning the distribution of flood control benefits of the project to income classes were nonexistent. Therefore, it was assumed that flood control benefits would accrue to income groups in proportion to the initial income distribution of the region. The flood control benefits forecast from the project are $15,558,598 on a present value basis. The costs associated with flood control consist of allocated investment costs and allocated operation and maintenance costs. The present value of annual operation and maintenance costs is $1,409,423, and the appropriate portions were distributed to income groups in the region on the same basis as investment costs. The overall income distribution effect of the flood control function is presented in Table 6.

Table 6. Distribution of net benefits from flood control by regional income classes

Class	Benefits	Investment cost	Operation and maintenance	Present value net benefits
	dollars			
Less than $3,000	4,045,235	408	20	4,044,807
$3,000–$10,000	9,801,917	6,724	326	9,794,867
Over $10,000	1,711,446	5,676	275	1,705,495

Water supply benefits were distributed to income classes on the basis of water expenditure by income class as a proxy for the amount of water used by each class. The calculations are shown in Table 7. It was assumed that the required 100 percent repayment would be financed by the locality through water charges and that the repayment would be in equal amounts over the entire 50-year period. The annual repayment, with interest on the unpaid balance, is approximately $97,000 per year. This amount was distributed on the basis of the percent of average water expenditures incurred by each income class. In other words, the actual reimbursement cost was distributed to regional income classes in the same manner in which benefits were distributed. Operation and maintenance costs are by law paid by the locality, so it was also assumed that these costs would be borne by regional income classes according to their water expenditures. The results of the calculations using these assumptions and the distribution of the present value of net benefits is presented in Table 8.

Table 7. Distribution of water supply expenditures and benefits by income class

Class	Average water expenditures per household	Households in region	Total water expenditures	Percent water expenditure	Present value of benefit to income class[a]
	dollars	*number*	*dollars*	*percent*	*dollars*
Less than $3,000	7.5	9,775	73,313	11	429,315
$3,000–$10,000	17.1	23,484	401,576	62	2,419,776
Over $10,000	40.0	4,256	170,240	26	1,014,745

[a] Based on $3,902,864 of present value water supply benefits.
Source: [27].

Recreation benefits were distributed to income classes on the basis of the percentage of visitors to federal reservoirs by income classes in 1960. However, only a portion of these benefits accrue to those people who live in the region. It was assumed that this proportion was 50 percent.[17] Recreation costs involve all three cost components. The distribution of the regional investment costs to income classes was given in Table 5. Assuming repayment is in equal installments over the entire time horizon, the annual amount to be repaid is $77,000. The law stipulates that the source of repayment must be limited to entrance and user fees collected at the project. (It is also possible to have repayment in the form of lands, but this possibility was ignored.) Therefore, the $77,000 was distributed to income classes on the basis of reservoir use by income classes.

[17] This figure was based upon an estimate made by the Pittsburgh District Office of the Army Corps of Engineers.

Table 8. Distribution of net benefits from water supply by regional income class

Class	Gross benefit	Investment cost	Reimbursement adjustment[a]	Operation cost	Present value of net benefits
			dollars		
Less than $3,000	429,315	35,936	+162,507	−17,003	247,875
$3,000–$10,000	2,419,776	592,944	+523,642	−95,835	1,399,025
Over $10,000	1,014,745	1,167,920	−704,204	−40,189	591,218

[a] Does not add to zero due to rounding.

Table 9. Distribution of net benefits from recreation by regional income class

Class	Benefit[a]	Investment cost	Reimbursement adjustment	Operating costs	Present value net benefits
			dollars		
Less than $3,000	365,322	28,357	+78,837	77,793	180,335
$3,000–$10,000	3,497,349	467,898	+556,147	744,740	1,728,564
Over $10,000	1,008,288	920,551	−634,974	214,709	508,002

[a] Based on 7.5 percent, 71.8 percent and 20.7 percent of visitors for the under $3,000, $3,000–10,000, and over $10,000 classes, respectively [29]; and $9,741,919 of present value recreation benefits.

Operation and maintenance costs are paid entirely by user fees, so these costs are also allocated on the basis of reservoir use by income class. However, because only 50 percent of total visitation was of a regional origin, only 50 percent of these costs were included in the calculations. The net benefit distribution effect of the recreation function is presented in Table 9.

Summary

The total net benefit distribution of the Stonewall Jackson project is presented in Table 10. The project has a positive effect on all income classes in the defined region because the region is not required, through either taxes or reimbursement, to pay even a major share of project costs. This is true even though the project from the national efficiency viewpoint is inefficient. The relative distribution of benefits tends to favor the middle income group with 64 percent of the total, but the upper income class receives the largest absolute value per household at $659 of *present value* impacts. Conversely, the lower income group receives the lowest absolute value per household. Table 10 also compares the relative distribution of income in the region before the project with the regional distribution of project benefits. The project would result in a slight distribution effect in favor of the lower income group. The results are of course valid only for the specific region defined and under the assumptions outlined.

Conclusion

For resource planning, acceptance of the proposition that governmental decisions are made within the framework of a multidimensional social welfare function implies that the distributional consequences of public programs are issues on a par with contributions to national economic growth. The thrust of this paper has been to reemphasize that evaluation of proposed governmental decisions should be carried out within such a framework. This position is based upon the value judgment that

Table 10. Net benefit distribution and income distribution effect of the Stonewall Jackson project by regional income class

Class	Percent of adjusted gross income in class	Present value of net benefit	Percent of net benefits by income class	Net benefits per household[a]
	percent	*dollars*	*percent*	*dollars*
Less than $3,000	10	4,473,017	22	458
$3,000–$10,000	62	12,922,456	64	550
Over $10,000	27	2,804,715	14	659
Total		20,200,188	100	

[a] Households in the region number 9,775; 23,484; and 4,256 for the respective income classes.

single-objective optimization exercises do not logically lead to welfare maximization. However, a multiobjective evaluation framework, although superior in design, requires clear conceptual separation of its component parts for purposes of measurement. A model designed to facilitate the measurement of often neglected equity consequences was set forth. A case study was then utilized to test the relevance of the model to empirical situations. That test pointed up the numerous empirical difficulties involved and the need for improved data on equity impacts.

The model postulated can be used to provide information on a number of different equity classifications. However, the appropriate number of dimensions to the social welfare function ultimately must be decided by the political process. Similarly, it is evident that *final* decisions on alternative courses of public action will not be made in terms of economic analysis. The results of evaluation done by economists will only serve as components in an overall decision-making framework. The trade-offs among such components are value judgments that must be defined externally. Whether or not a priori trade-off weights can be defined by the political process for the various objectives of a multidimensional function, improved information about program impacts in terms of all relevant objectives is needed. This will permit the quantitative interrelationships to be highlighted and the social opportunity cost of alternatives to be made more explicit. Planners and elected officials can then make the trade-offs necessary to reach decisions, and improved analysis of those decisions by their respective constituencies can take place [11]. Furthermore, more reasoned and responsible judgments on program cost sharing and reimbursement can result from increased knowledge of the nature and extent of program impacts on various governmental and private group interests.

In summary, the profession's traditional ideas of what constitutes welfare maximization and the methods of empirically implementing our progress toward that state need to be substantially changed. To that end, this paper joins an emerging group [13, 17, 18, 22, 31, 32] to urge that our applied tools of evaluation be altered in an effort to better reflect these concerns.

Price Elasticities from Panel Data: Meat, Poultry, and Fish*

JOSEPH C. PURCELL AND ROBERT RAUNIKAR

National aggregate time series data are not amenable to tracing the consumer response to price changes as these changes occur in the market. This paper is designed to stimulate interest in the development of alternative sources of data and modification in estimating procedures to more nearly approach reality in estimating price-quantity relationships. The analysis was based on data obtained from a group of consuming units on quantities of meats purchased and prices paid. The procedure was designed to trace the consumer response to price changes approximately as they occurred over time.

CONSUMER RESPONSE to changes in the price of foods and other commodities is a problem of long-standing concern to agricultural economists. The problem is generally posed in terms of price elasticities of demand. Parameters desired are simply the changes in quantities purchased by consumers associated with a given change in price, or a schedule of quantities associated with a schedule of prices assuming all other variates remain unchanged.

After considerable time and effort devoted to the problem, there is still limited information available that is widely accepted on specific price-quantity relationships. The major limitation lies in the dearth and inadequacy of data necessary to estimate these relationships. Although pricing experiments [3, 6] have been accomplished, the problem is basically not amenable to experimental control procedures.

Observations generated by the market system have provided the primary source of data for analysis. However, these data are generally time series in nature and available only on a national aggregate basis. Estimates are made (usually by federal agencies) on quantities of commodities produced, aggregate disappearance, and average price at different times and locations. Estimates are also available on population, income, and other variates that influence demand.

Analyses of these types of data with respect to theoretical economic relationships have raised a host of questions regarding estimating procedures and interpretation and have contributed to the development of modified statistical procedures [4, 7] that attempt to deal with statistical problems inherent in the data. Some of the problems of estimation based on aggregate time series data include: (1) a limited range in postulated explanatory variates; (2) multicollinearity in explanatory variates; (3) lagged adjustment in response; and (4) gross averages for long time periods that conceal many individual changes. Perhaps too much effort has been devoted to estimating procedures relative to exploring and developing alternative data sources.

Orcutt [8], in a study concerned with basic data requirements, concluded that social science will remain stunted until better ways are found to secure essential empirical evidence than seems possible as long as dependence on government data collection persists, because such data collection of necessity is done for other purposes and cannot be controlled effectively by researchers. According to Orcutt, basic research aims at discovering the response characteristics of consuming units, firms, governments, and other key actors in social systems. Effective study requires following consuming units, firms, etc., over time rather than following geographic areas over time. Also, with a nonexperimental statistical approach it is frequently essential to work with disaggregated data because of consideration of degrees of freedom, use of control groups, avoidance of multicollinearity, and range in variables of interest.

This paper presents an alternative with respect to source and nature of the data and a more realistic time period. It also raises some questions concerning traditional arguments of consumer response in the short, intermediate, and long run; the nature of the adjustment process; and reversibility of demand functions.

Meat—subdivided into beef and veal, pork,

* Georgia Agricultural Experiment Station Journal Series Paper 954. The authors are indebted to an anonymous reviewer for pointing out an inappropriate formulation in the original draft of this paper.

JOSEPH C. PURCELL *is professor of agricultural economics and Robert Raunikar is associate professor of agricultural economics at the University of Georgia.*

poultry, meat mixtures, and fish—was selected for analysis. Meat and its subgroups are subject to frequent price changes compared with other major food commodities. The various kinds of meats are highly substitutable with respect to nutrition and are often interchanged for the sake of variety.

Questions Concerning Price-Quantity Relationships

The question of lagged response to price changes is based primarily on the argument that the full response to a price change is related to time elapsed [7]. Habit and customs in consumption patterns and limited knowledge concerning price changes are alleged to retard consumer response.

Time necessary to develop, promote, and market acceptable substitutes is a factor in consumer response to prices in the longer run. Price supports for cotton and butterfat, for example, provided an incentive for developing substitutes acceptable to consumers. The type of pricing policy, persistency of price levels, and substitution are additional factors that deserve more attention in demand analysis.

Uvacek [12] has posed a question regarding the reversibility of price-quantity relationships. Many commodities, including most meats, are subject to periods of increasing and decreasing prices (or supplies) because of the cyclical nature of production. It might be hypothesized that consumers are responsive to falling prices (increased supplies) for highly preferred foods such as meats but are more reluctant to reduce consumption when prices begin to rise.

Analysts generally have confined their efforts to observations on average prices and quantities for specified time periods, most frequently the year. Time periods of a quarter and a month (in some cases four weeks) have also been analyzed. Ladd and Martin [7] utilized quarterly and four-week data from the Michigan State University Consumer Panel to evaluate alternative estimating procedures with respect to lag in consumer response to price and concluded that most of the adjustment occurs within one year and in some cases does not exceed one month. The same study also indicated that the addition of lagged quantities as an independent variate does not necessarily reduce autocorrelation in the errors.

This paper is predicated on the assertion that the week is the relevant planning and action period with regard to both food purchasing and pricing policy. Changes occur (or are subject to do so) in a time sequence from week to week. Prices can be changed more than once a week, but generally prices are announced by retail stores through newspapers and other news media once each week.

Source of Data

The source of data for this study was a panel of consumers located in Atlanta, Georgia [10]. Food purchases were reported weekly over a five-year period, 1958 through 1962. Data reported included quantity, price, expenditure, and a detailed description as to form, size, and type package. Detailed data were also maintained with respect to household composition, race, income, education, etc. The panel was maintained with replacement at approximately 300 households, and 160 households remained on the panel the entire five years.

Panel data have certain advantages and disadvantages compared with traditional data sources. Specific consuming units react to changes in price or other changes in the market place. This negates the question of simultaneity or whether supply is predetermined, as is the case with national aggregate time series data.[1] It is obvious in this case that prices are predetermined and consumers react to prices.

Panel data also permit observations on consuming units at approximately the time (week) changes occur. In the case of most aggregate market data, only average prices and average quantities for longer time periods can be observed [2]. Also, the panel data permit aggregation for any time period from one week to five years.

The main disadvantage of panel data is the limited population that is represented. Although there is a national panel, maintained by the Market Research Corporation of America, the data are not readily available to most analysts.

Statistical Procedure

The statistical procedure was designed to trace the reaction of a group of consuming units of known characteristics to price changes approximately as they occurred in the market. A first-difference (week-to-week changes) basic analysis was employed.

[1] Fox [5] maintains that in the case of national aggregates for most farm commodities, quantity is largely predetermined. Thus, price-quantity observations approximate a demand schedule.

The model was of the form

$$Q_{it} - Q_{it-1} = a_i + b_i(P_{it} - P_{it-1}) + c_j(P_{jt} - P_{jt-1}) + u.$$

The dependent term, $Q_{it}-Q_{it-1}$, represents the change in purchases of a particular kind of meat (i) from the previous week.

The constant a represents trend in a first-difference equation. For equation in logarithms, the antilogarithm of $(a+2)$ minus 100 represents percentage trend [4, p. 43].

$P_{it}-P_{it-1}$ represents the change in the price of the same kind of meat from the previous week. The coefficient b is an estimate of the effect of a price change on the quantity purchased. For equations in logarithms, b is an estimate of the price elasticity of demand.

$P_{jt}-P_{jt-1}$ represents the change in the simple weighted average price of substitute meats. For equations in logarithms, c is an estimate of the cross-price elasticity of demand.

The u term is a disturbance or residual assumed to be randomly distributed.[2] A basic assumption of the model is that other variates (household composition, income, etc.) do not change in sufficient magnitude from week to week to influence week-to-week changes in meat purchases. Also, the constant a depicts trend over time that may be attributed to these variates. Seasonal adjustment does occur from week to week but is assumed to be a gradual process.

Since a relatively large number (259) of observations were available, positive and negative price changes were analyzed separately to test the reversibility of demand functions.

The same model was also employed to analyze quarterly data with respect to response in average levels of purchases to changes in average prices. A seasonal variate was added to the model for quarterly data. Quarterly data for common quarters (year to year) were utilized to estimate consumer response to changes in average prices from year to year. The Index of Consumer Prices was added to allow for changes in the price level from year to year. This permitted comparisons of initial consumer response to price changes, and average quantities and prices for longer time periods.

[2] A transformation to first differences is suggested for time-sequential data where serial correlation in the residuals is expected [4, p. 30].

Results

Table 1 shows basic characteristics of the data upon which the analysis was based. Week-to-week changes in quantity relative to the mean quantity were considerably larger than price variation. Relative price variability was greater for fish and poultry than for the other meats. Variability in quantity relative to the mean was also largest for poultry.

Table 1. Characteristics of data related to week-to-week variation in prices and quantities of meat purchased, Atlanta Consumer Panel

Meat	Price		Quantity		Correlation between explanatory variates[b]
	Mean	Variation[a]	Mean	Variation[a]	
	dollars per pound	*percent*	*pounds per household*	*percent*	
Beef and veal	0.627	3.56	2.73	12.33	−0.11°
Pork	0.508	3.40	3.66	11.21	0.04°
Poultry	0.364	5.42	2.39	19.67	0.07°
Meat mixtures[c]	0.606	2.85	0.71	8.26	0.09°
Fish[d]	0.504	6.41	0.69	11.28	0.78**

[a] Mean first differences (week to week) relative to mean price and quantity.
[b] $(P_{it}-P_{it-1})$ and $(P_{jt}-P_{jt-1})$, where P_i=price of meat i, P_j =weighted price of substitute meats.
[c] Includes weiners, bologna, and other meat mixtures (largely beef and pork).
[d] Includes finfish and shellfish.
** Significant at the 0.01 level.
° Nonsignificant at the 0.05 level.

The last column of Table 1 indicates the magnitude of the multicollinearity problem between the postulated explanatory variates. Only for fish were price differences between week t and week t-1 highly correlated with differences in the weighted prices of substitute meats. Price changes (as well as quantity changes) tended to alternate between positive and negative. For example, price changes for beef alternated from positive to negative in nearly 75 percent of the week-to-week changes.

Estimated price elasticities of demand and cross-elasticities with substitutes based on week-to-week price changes in logarithms are shown in Table 2. All of the direct price elasticities were of the expected negative sign and all were highly significant ($P<0.001$). Of the five meat groups, pork was most responsive and poultry least responsive to price changes. Cross-elasticities were not consistent with respect to the expected positive sign. Poultry was most responsive (with the expected sign) to changes in the weighted price of substitutes. The negative response in purchases of beef and veal and

Table 2. Estimated price elasticities of demand for meat at retail based on week-to-week first difference price changes, Atlanta Consumer Panel

Meat quantity (dependent)	Price elasticity		Cross-price elasticity[b]		R^2
	Estimate	t ratio[a]	Estimate	t ratio[a]	
Beef and veal	−1.36	9.81	−0.46	2.08	0.28
Pork	−1.66	12.86	0.09	0.46	0.39
Poultry	−0.79	4.54	1.95	4.36	0.13
Meat mixtures	−1.02	5.72	−0.58	3.07	0.15
Fish	−1.58	8.87	0.42	1.85	0.36

[a] Approximate significant levels for t: $t_{0.001}=3.33$, $t_{0.01}=2.59$, $t_{0.05}=1.97$.
[b] Based on a simple weighted average price of substitute meats.

meat mixtures to prices of substitutes might reflect overall adjustment in meat purchases as prices change. Average prices of beef and veal and meat mixtures were appreciably higher than the other meat groups.

Estimated price elasticities of demand for meats in response to positive and negative price changes are shown in Table 3. Except for poultry and fish, the indicated response to negative price changes was greater than the elasticity in response to positive price changes. The difference was greater for pork and meat mixtures. Poultry differed from the other meat groups in that a greater response in purchases to positive price changes was indicated; also, poultry was significantly responsive to changes in the price of substitutes.

Price elasticities of demand for meat based on quarter-to-quarter and year-to-year (common quarter) changes in average price levels are shown in Table 4. Except for poultry, the longer time periods yielded lower estimates of price elasticities of demand. All direct price elasticities were of the expected sign. However, because the number of observations was limited, the statistical reliability was much weaker than the analysis of weekly data.

Table 4. Estimated price elasticities of demand for meat at retail, based on quarter first difference in average prices and common quarter year-to-year average prices, Atlanta Consumer Panel

Meat quantity (dependent)	Quarter to quarter			Year to year

Poultry	−0.71	3.66	0.93	−0.94	7.01	0.87
Meat mixtures	−1.00	1.33	0.83	−0.53	0.54	0.16
Fish	−0.82	2.61	0.87	−0.36	1.08	0.25

[a] Approximate significant levels for t: $t_{0.001}=4.22$, $t_{0.01}=3.01$, $t_{0.05}=2.16$.

Implications and Limitations

The major contribution of the data, procedure, and results reported in this paper is perhaps to suggest additional research in the area of consumer response to price changes. Although the results were generally statistically reliable, the parameter estimates are based on a relatively small sample of a population in a specific geographic area. Thus, the results in some instances may not be applicable to populations in different locations or different time periods. Meat is subject to frequent and well-publicized[3] price changes. Prices paid for a par-

[b] Approximate significant levels for t: $t_{0.001}=3.38$, $t_{0.01}=2.62$, $t_{0.05}=1.98$ (observations ranged from 116 to 138 with 3 constants estimated).

ticular kind of meat (beef, pork, poultry, meat mixtures, and fish) is a composite weighted price paid by the panel, although it is recognized that the composition of meat purchases might influence the average price paid.[4]

Consumers react to changes in the price of meats approximately according to theoretical expectations as the changes occur in the market, with a high degree of statistical reliability. Except for poultry, meat purchases were not significantly responsive to changes in the price of substitutes either individually or as a group. This response pattern may be in part attributed to the fact that the average price paid for poultry was appreciably below that of the other meat groups. Poultry was least responsive to changes in its own price and most responsive to changes in the price of substitutes. Although poultry is a relatively inexpensive meat, consumers apparently prefer variety in meat purchases. During the period between 1945 and 1969, poultry (broilers in particular) was substituted for pork as prices of poultry declined relative to pork [9]. However, as the process advanced, greater resistance to further substitution was indicated. This principle is expected to apply to other segments of the meat industry as inroads into the meat market are attempted through increased output and reduced prices.

Results of this study suggest that consumer response (absolute elasticity) to negative price changes is greater than the response to positive price changes for all of the meat groups except poultry. Thus, there is some evidence that the demand relationships (price-quantity) are irreversible for some meats. Consumers indicated more resistance to reduce purchases in response to rising prices than to increase purchases in response to falling prices with comparable price changes.

Irreversible demand relationships have important implications to the various segments of the meat, poultry, and fishery industries. For example, higher levels of consumption gained on the downswing of a price cycle (increasing production) are only partially lost when prices return to the original level on the upswing of the cycle (decreasing production). Thus, the upswing of the production cycle tends to increase demand. Or in terms of price flexibilities, prices rise more rapidly on the downswing of the production cycle than prices fall on the upswing of the production cycle. Irreversibility of demand relationships would also have important implications for price forecasting, as a different demand elasticity (or price flexibility) may apply depending on the direction of change. This suggested pattern of price-quantity relationships deserves further investigation.

Decisions on the part of consumers concerning meat purchases are made generally each week.[5] Also, the week is a relevant period for price changes in the market in response to supply and demand forces. Observations on longer time periods (month, quarter, year) constitute averages for the period, and thus, the responsiveness of consumers to week-to-week price changes is lost in the analysis of such data. Although subject to a small number of observations on quarter-to-quarter and year-to-year observations for common quarters, the results of this study indicate price elasticities of demand for meats are smaller (absolute values) for the longer time periods. However, these results do not necessarily contradict the concept that persistent relatively high (or low) prices encourage the development of substitutes (or substitution for other commodities) and thus lead to larger absolute price elasticities in the long run. These conditions simply did not exist in the market analyzed.

Summary

The purpose of this study was to estimate consumer response to price changes for meats approximately as changes occurred in the market. Estimated consumer response (price elasticities) in meat purchases to price differences were of the expected sign with a generally high degree of statistical reliability. Except in the case of poultry, the meat groups analyzed were not generally responsive (expected sign) to changes in the price of substitute meats. Poultry, a relatively inexpensive meat was least responsive to change in its own price and most responsive to change in the price of substitutes. This pattern indicates a preference for variety in meat purchases within a fairly wide range of price differences. A separate analysis of positive and negative price

is a prime example of advance information available to consumers on prices of meats.

[4] This is a limitation of most data and is not unique to panel data; for example, in national aggregate data the quality of meat is subject to change over time.

[5] Consumption does not necessarily coincide with purchases week by week, as meat may be stored from week to week and longer periods if frozen.

changes by week suggested irreversible demand relations with larger elasticities associated with negative price changes. Estimates of price elasticities were generally progressively smaller (absolute) for the longer time periods—quarter to quarter and year to year for common quarters.

Additional research is suggested to trace out more adequately consumer response to price changes as they occur in the market. It is also suggested that pricing policy and persistency in price levels may play an important role in consumer response to prices and substitution over long time periods. Lack of data on specific consuming units and insufficient range in prices (variation in the postulated explanatory variates) appear to be the major limiting factors with respect to estimating price-quantity relationships. Pricing experiments in conjunction with maintaining data on specific consuming units (consumer panel) are suggested as an alternative to provide data for analysis of price-quantity relationships. A small number of pricing experiments have been conducted and consumer panels have been operated in different locations for limited time periods but not in conjunction with each other.

Reservation Prices on Credit Use: A Measure of Response to Uncertainty

PETER J. BARRY AND C. B. BAKER

Liquidity in the form of reserved credit is valuable to a business manager because it is available to counter uncertain expectations. This paper investigates the definition and method of estimating values or reservation prices associated with firm liquidity provided by unused credit. A multiperiod linear programming model is taken to reflect the behavior of decision makers in empirically observed situations. Credit reservation prices of decision makers were inferred by comparing growth information for real borrowers with growth information generated by the comparable model at alternative reservation prices. This method succeeded in associating a high credit reservation price with the conservative borrower and low credit reservation prices with a more liberal borrower.

NUMEROUS FIRM growth models have shown that surprisingly rapid growth is possible, e.g., [2, 9]. However, it is difficult to explain why firms do not generally match the model results. Often this discrepancy may arise from failure to recognize the manager's response to numerous sources of business and financial risk and to alternative means of coping with these risks. Previous articles have stressed the need for incorporating the effects of financial strategies and liquidity demands into firm decision making and financial management research [1, 2, 3]. This paper reports a means of estimating values or reservation prices associated with the liquidity provided by unused credit—credit defined as the capacity to borrow.

Problem and Methodology

Value of credit liquidity

Capital limits generally constrain farm planning. Because they are modified by borrowing, these limits are affected by external and internal credit rationing. External credit rationing exists when the borrower has exhausted all sources of loanable funds but still finds the marginal value product of borrowing to exceed the marginal cost of borrowing (both interest and noninterest costs). This situation reflects requirements of lending institutions, loanable funds supplies, or, perhaps most important, the lender's evaluation of the amount and structure of a farmer's credit [1, pp. 518–519; 11; 16].[1]

Previous research [6, 7, 8], as well as empirical observation of debt-equity ratios [10, 12, 13], suggests that farmers do not in general utilize their credit in borrowing to the point where external credit rationing becomes an effective constraint. Self-imposed limitations on credit use provide liquidity in the form of a credit reserve and thus limit exposure of the borrower's equity. Hence, debt aversion is a form of risk aversion and thereby constitutes an important alternative response to uncertainty.

The decision maker must consider potential sources of uncertainty and the alternatives for countering uncertainty.[2] Farm business risks are associated with uncertainty in prices, yields, technology, and general economic conditions, as well as with legal and other institutional uncertainty and uncertain expectations on the behavior of people upon whom the firm may depend. Business risks interact with risks inherent in the financial strategies employed in farm planning. Financial strategies involve financial risks which arise from the use of leverage in the capital structure [3]. We assume that risk aversion is pervasive in economic activities at all income levels, with the possible exception that small stake gambling may be a pleasurable activity for many individuals.

Risk aversion can be expressed in the production, market, and financial organization of the farm firm. In production, risk aversion appears in the search for and adoption of organizational flexibility, product diversification, and informal production insurance (e.g., pesticides and supplemental irrigation), as well as in choices of enterprises with low price and/or yield variability. In marketing, risk aversion can explain the use of forward and futures contracts and, to

[1] This situation bears some resemblance to the corporate cost of capital controversy [17]. We hypothesize that the lender's reactions to different capital structures may raise the firm's cost of capital. This reaction occurs not necessarily as higher interest rates, but in terms of lending limits.

PETER J. BARRY *is assistant professor of agricultural economics at Texas A & M University.* C. B. BAKER *is professor of agricultural economics at the University of Illinois.*

[2] The theoretical development of decision making under uncertainty is not reviewed here. The reader is referred to the many references available on this subject, e.g., [17].

ome degree, participation in government programs. Financial alternatives for averting risks nclude formal insurance, assets held for their iquidity attributes, and credit held in reserve.

The payoffs associated with these alternatives ire difficult to measure. Furthermore, financial ilternatives for averting risk are often not indeendent of alternatives in other economic areas f the firm. Trade-offs generally exist between neans of averting risks in the production, narketing, and financial organization of the irm. Thus, emphasis on one means of countering uncertainty (e.g., liquidity) may allow a lecision maker to make more daring choices in ther firm areas (e.g., product specialization).

It is reasonable to expect cash grain farmers o be homogeneous with respect to many of the ilternatives for averting risk. Cropping patterns ind practices among farmers in a given geographic region are in general similar. Most armers participate to a similar degree in government programs. Few farmers hedge their rop or use other forward contracts. Most armers use formal insurance in insurable situaions: life, fire, hail, and other personal property or liability contingenices.

Given homogeneity in the use of these means o counter uncertainty, variation in the demand or credit liquidity may be the most visible mpirical feature. In addition, liquidity is robably the most general means of countering ıncertainty and provides a minimum effect on he economic organization of the firm. At first lance the expected effect might occur only as educed scale. However, Baker [1] has shown hat liquidity attributes of the firm's organizaion may logically be expected to influence illocative decisions in production, marketing, nvestment, and finance. Thus, the liquidity issociated with unused credit, together with mpirical observations of debt aversion, sugests that credit maintained as a reserve has value to the decision maker.

Equilibrium in credit use

In an optimal allocation of credit between use or loans and use in reserve the decision maker must consider the value of the credit reserve as well as the value of the borrowed funds. Presumably the credit reservation price rises as further borrowing depletes the credit reserve [3]. Conversely, the value of additional units of unused credit declines as borrowing declines.

This situation is portrayed by liquidity value curve U_1 U_1 in Figure 1. The more averse the

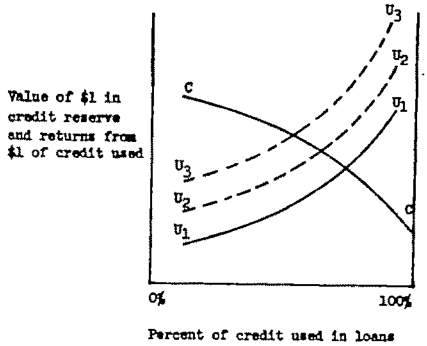

Figure 1. Credit-liquidity equilibrium

decision maker is to debt, the higher is the position of UU. It seems plausible to assume that an individual's liquidity value curve could shift and change shape over time as a result of experience, age, preference changes, or other changes that alter the importance of risk to him.

It may pay the farmer to borrow because of leverage attained through the use of borrowed funds. Thus, the cost of maintaining liquidity in the form of unused credit is an opportunity cost reflecting the return foregone by rejection of borrowing as an alterntive use of credit. The law of diminishing marginal returns indicates that the returns from successive units of resources and resource services acquired with the use of loan proceeds (i.e., used credit) will decline at an accelerating rate, as indicated by liquidity cost curve CC in Figure 1.

The intersection of the liquidity value and liquidity cost curves indicates a credit-liquidity equilibrium for a decision maker. The marginal value and marginal cost of unused credit are equal at this point.

Estimation of reservation prices

Credit reservation prices could be easily determined if farmers could accurately specify their minimum required rates of return on borrowed funds.[3] But farmers in general are not readily prepared to provide such information. Hence, an alternative method of inference was devised.

Information on decision elements and out-

[3] The reservation price approach is comparable to the required rate of return on investments in capital budgeting techniques. However, the reservation price approach may provide greater explanation of decision-making behavior since it reflects the value of a specific means of countering uncertainty—a liquid credit reserve.

comes for a cash grain farm in Central Illinois was empirically derived from historic records. This information included input data, resource levels, consumption patterns, credit use over time, rates of firm growth, and the production and market organization. This information was incorporated in a multiperiod linear programming model to portray a farm decision-making situation over a historical time period. Thus the performance of the farm firm was known.

Risk aversion was reflected in the valuation of a credit reserve maintained throughout the planning horizon of the model. The objective specified in the model included asset equity measured at the end of the planning period, consumption during the planning period, and liquidity management, as reflected by the reservation price for credit. A specified consumption function determined the allocation of disposable income between consumption and savings.

Since financial protection provided by liquidity is an important decision objective, reservation prices were introduced as positive objective function values in slack vectors of credit constraints in the programming model. Other means could have been used to identify reservation prices for credit: the addition of a noninterest cost to the interest rate on borrowed funds or the specification of a negative rate in the objective function for borrowing activities. Alternatively, one might have included a farmer-imposed credit constraint in the model, using shadow prices on this constraint as measures of reservation price on credit.

Production and marketing alternatives were limited in the model to allow emphasis on alternative financial specifications. The limited alternatives also accorded well with empirical experiences of cash grain farmers in Central Illinois.

Reservation prices were inferred for decision makers by comparing growth information for real borrowers with growth information generated by the comparable models at alternative reservation prices. Since costs and return per production unit were assumed given over time, a constant liquidity cost function was defined. Consequently the parametric variations in reservation price implied a ranging of the liquidity value curve as indicated by curves U_2 and U_3 in Figure 1. Thus, the model solutions at varying credit reservation prices reflect equilibrium points between a constant liquidity cost function and a shifting liquidity value function. In the process the liquidity cost curve for the planning horizon is traced out with linear segments because the linear programming technique was used. Given these equilibrium points between the value and quantity of credit reserved, the task is to find on the derived cost curve the price or range of prices that is consistent with the quantity of credit reserved by real world decision makers.

The Linear Programming Model

The linear programming model yielded a mutually optimal solution among production, marketing, investment, and financing decisions. The choice of linear programming implies that farmers are optimizers subject to decision elements, i.e., alternatives, constraints, and objectives, that can be accurately portrayed in the model. Furthermore, in using linear programming, one assumes that land investments can be treated on an incremental basis with emphasis on total investment within the planning horizon.

The linear programming model covered 21 years, divided into seven three-year periods.[4] Coefficients, stated in annual terms, were averages over each three-year period. The operator began as a full tenant. Data were collected from summaries of farm records for the 1948–1968 period. They included crop yields and prices, cost of production, land values, consumption functions, tax rates, labor requirements and wage rates. Each period of the model was divided into four seasons to allow for detailed intrayear cash flows.

Components of the model are identified for two periods in Table 1. The columns and rows for respective periods represent blocks of activities or constraints. Hence the letters refer to submatrices of coefficients. Interperiod transfers are shown for resources, debt, and cash. The objective was postulated as a maximum of the value of all asserts minus debts at the end of the planning period, plus the value of all consumption expenditures above a specified minimum during the planning period, plus the value of credit reserves during the planning period, subject to constraints in the categories indicated.

Production is constrained by resource limits on land, labor, and capital capacities. Production constraints may be increased over time by investment choices and labor hiring. Financial

[4] Complete specification of the linear programming model may be found in [4].

Table 1. Outline of linear programming model used to infer credit reservation prices

Constraint	Produce and sell products	Buy resources		Borrow (short term)	Service debt		Pay tax, consume and save	Transfer cash	Reserve credit	Constraint

[a] n = respective period $(1 \cdots N)$

components in the constraint set include cash, credit, debt, and tax constraints. Cash rows account for the cash flow of the business over time. Non-real estate credit and real estate credit are available for borrowing or for reserve. The credit constraints are modified by an asset acquisition, income expectations, borrowing, repayment commitments, and appreciation or depreciation of capital values as these materialize over the planning horizon. The debt row accounts for debt repayment or transfer to the following period.

Tax bracket rows account for all activities that affect taxable income. A minimum level of consumption, which may increase over time, is required before any funds are available to add resources to the firm.

A corn-corn-soybeans rotation is specified as the production and marketing activity in each period of the model. Growing crops use land, labor, cash, and machinery and storage capacity. They generate cash, taxable income, and non-real estate credit.

Resource acquisition includes labor hiring and investment in capital assets. Investment choices were limited to land purchase accompanied by required additions of machinery and storage capacity. This limitation accords with the real world of the cash grain farmer. Cash purchase, mortgage financing, and intermediate loans were cast as financing alternatives for the investments. Objective function entries represent the asset's value, appreciated or depreciated, at the end of the planning period. Credit is absorbed by borrowing to finance assets and is further reduced by debt repayment commitments [11]. Credit is modified in following periods as asset equity is increased by debt repayments and by the appreciation and depreciation of asset values. Depreciable assets are maintained by depreciation allowance on cash in the production activities of following periods. Tax row entries reflect tax deductible expenses associated with investments: interest on debt, taxes, and depreciation.

Short-term borrowing generates cash and debt balances and absorbs non-real estate credit at a specified rate. Debt servicing activities allow repayments of principle and interest or transferral of debt and accrued interest to the following period. In the final period the objective function is reduced for each dollar of outstanding debt.

Each dollar of taxable income above the minimum consumption level is divided among taxes, consumption, and savings. Consumption and taxes are specified respectively by a declining marginal propensity to consume and a progressive tax rate structure.[5] The consumption schedule also declines over time, reflecting a time preference for early consumption. The respective period's consumption is reflected in values of the objective function entries.

[5] See [4, 15] for further elaborations on tax and consumption specifications in linear programming models.

Table 2. Inferred credit reservation prices for case farms

	Borrower One	Credit reservation prices		Borrower Two	Credit reservation prices	
		.25	.30		.01–.02	.03
Borrowing period, years[a]	16	15	15	7	6	6
Beginning net worth, dollars	13,087	17,469	17,469	21,504	39,030	38,970
Ending net worth, dollars	86,143	67,513	64,111	108,070	84,506	80,703
Net worth growth, dollars	73,056	50,044	46,642	86,556	56,476	41,733
Average annual net worth growth, dollars	4,583	3,336	3,109	12,365	7,579	6,955
Average acreage farmed annually, acres	485	347	341	667	406	387
Average annual net worth growth per acre, dollars[b]	9.45	9.61	9.11	18.54	18.66	17.97

[a] Growth data for shorter model-planning horizons were calculated to validate comparison with real growth situations involving similar time periods and similar stages within the process of growth.
[b] Average annual growth in net worth is determined by dividing total net worth growth by the number of years in the model. Average annual net worth growth is then divided by the number of acres farmed annually in order to determine average annual net worth growth per acre.

Vectors are provided to transfer surplus cash savings from season to season, period to period, and to the objective function at the end of the planning horizon. Credit reserve activities allow the reservation of non-real estate credit and real estate credit as a source of firm liquidity.

Empirical Application

The results of the preconstructed model are compared with the growth of two cash grain farms for which information on growth and credit use was gathered directly from the financial records of a production credit association from whom they had borrowed continuously. The model was so specified as to resemble the actual farms over the historical period, in terms of their pattern of land control. The model solution indicated a transition from tenant to part-owner status, with owned land about one quarter of total land operated. The case farms also acquired greater ownership over time, with owned land less than one quarter of the total land operated.

Growth was measured on a per acre basis to account for differences in initial farm size between the model and case farms. This is warranted by empirical evidence which suggests that constant returns to size may exist over the limits of production conditions of this study [5, 14]. Thus, with discrepancies in initial farm size removed and other variables held constant, differences in reservation prices on credit can explain differences in growth rates. Furthermore, because of differences in the length of historical period between the model and case farms, growth is measured on the basis of average annual net worth growth per acre.

Table 2 reports growth information for the case farms and growth information generated by the comparable model at the indicated reservation prices. Borrower One's net worth increased by $73,056 over a 16-year period, an average annual growth of $4,583. Over this period he farmed an average of 485 crop acres annually. Thus, his average annual net worth growth per acre was $9.45. Borrower One's growth rate was associated with a credit reservation price in the area of .25 to .30, since model growth rates were $9.61 and $9.11 for these respective prices. This reservation price range implies a relatively high degree of debt aversion for Borrower One. His lender described him as a "conservative" credit user. This was further substantiated by his relatively high average annual ratio of net worth to total assets (.905) and a relatively low index of available non-real estate credit that was actually used (29.9 percent).[6]

Borrower Two's net worth increased by $86,566 over a seven-year period, an average annual growth of $12,365. Over this period he farmed an average of 667 acres annually, with an average annual growth in net worth per acre of $18.54. Borrower Two's growth rate was associated with a credit reservation price in the range .01 to .03, which implies a relatively low degree of debt aversion. His lender described

[6] Estimates of each borrower's available credit were based on rules of thumb reflecting lender evaluation of the farmer's assets and income expectations from production activities. Since these rules of thumb were applied consistently over time and between different borrowers, each borrower's credit was measured on a common basis. Available credit was used at various rates, depending on the amount and purpose of historical borrowing.

him as a "liberal" credit user. This is substantiated by his relatively low average annual equity ratio (.496) and a relatively high index of non-real estate credit use (94.9 percent).

Concluding Comments

Debt aversion was considered as the sole variable with which to distinguish response to uncertain expectations by cash grain farmers. Such an assumption might not hold as well for other types of farmers. Future research might usefully attempt to explain risk-averting strategies for other farm types and analyze the risk-return payoffs associated with combinations of risk-averting alternatives. For example, skills in hedging on the futures market may diminish the need for credit liquidity; or more comprehensive insurance schemes may reduce the value of credit liquidity for individual managers. Finally, the influence of each risk-averting alternative on the credit capacity of the firm should not be neglected.

The validity of the inference method in this study depends upon the large number of parameter values, activities, constraints, and objectives taken as given in order to imply a credit reservation price for a decision maker. To achieve a degree of empirical generality it would be useful to have estimates of the influence on growth of factors other than liquidity, including random disturbances. Linear programming models as generally used do not generate error estimates associated with results. Useful results might be obtained by inputting specified parameters at values determined by sampling from derived probability distributions.

Financial management research as well as education activities with farmers and lenders must increasingly take into account the manager's attitude toward risk and alternatives for countering risk. The decision maker's response to research results, extension advice, and other management council often depends on both the farmer's and the adviser's recognition of uncertainty associated with the recommendations.

Finally, information on credit reservation prices prevailing in agriculture may allow more assessment of the impact of certain macro finance policies. For example, if the total flow of funds into agriculture were increased, knowledge of debt aversion behavior would help in forming estimates of the pattern of use of funds and might enable more precise identification of emerging, successful farmers.

Effects of Split-Demand and Slaughter-Capacity Assumptions on Optimal Locations of Cattle Feeding*

LARRY N. LANGEMEIER AND ROBERT M. FINLEY

Many studies have concentrated on the optimal location of cattle feeding. Two major limitations of such studies have been (1) reliance on a single demand function for beef and (2) failure to consider existing slaughter capacities. By utilizing separated or split-demand functions for beef and explicitly accounting for present regional slaughter capacity, quite different patterns of beef feeding emerge. In comparison with actual feedlot locations, the models used showed considerable improvement over most previous models. More importantly, results compare favorably with recent trends in the location of cattle feeding.

FACTORS AFFECTING location of feedlots in various regions of the country have been the subject of some study and much speculation. Studies by Judge and Wallace [2], Williams and Dietrich [9] and Rizek, Judge, and Havlicek [5] have contributed to an understanding of the interrelationships of the complex livestock economy. Research efforts by King and Schrader [3, 6, 7] are especially important, primarily because they not only considered the optimal transportation patterns of beef but also incorporated cattle-feeding activities in the models. Although these studies were innovative and of great interest from a methodological viewpoint, "optimal" marketings sometimes bore little relationship to trends. Our contention is that two major variables must be introduced in the models to make such studies of practical value to those interested in the cattle-feeding industry:

(1) "Splitting" the demand for beef into two distinct demands—fed beef and nonfed beef components.

(2) Accounting for present regional slaughter capacity.

Unless those constraints are included in a spatial equilibrium model, the results may be misleading and of only limited value in an applied sense. Therefore, a model of the cattle feeding industry is presented incorporating the split-demand and slaughter-capacity assumptions. The model is patterned basically after previous models to allow comparisons, if that is appropriate.

The Spatial Equilibrium Model

A single demand for beef seems to be unrealistic, considering that consumers differentiate between different qualities of beef and that the important variables of price, income, and population influencing this pattern of beef consumption vary widely among areas. In this model a region's demand for beef was separated into two distinct but aggregative entities—a demand for fed beef and a demand for nonfed beef. This separation of total beef demand eliminates the possibility that a region's beef consumption might be satisfied entirely by nonfed beef, which otherwise could occur in regions that are low in population and/or have a large number of beef and dairy cows.

Neither price nor quantity data were considered adequate to fit statistical demand functions for each region. Therefore, the demand equations were derived from a simultaneous equation analysis of the beef industry by Langemeier and Thompson [4]. The respective beef demands on a per capita basis were:

$$f = -28.3 - 0.66P^f + 0.30P^n + 0.068I$$

$$n = 47.7 + 0.40P^f - 0.52P^n - 0.017I$$

where

f = per capita demand for fed beef,
n = per capita demand for nonfed beef,
P^f = retail price of fed beef,
P^n = retail price of nonfed beef, and
I = per capita disposable income.

Demand elasticities derived from the above equations were used to adjust the demand equations to the 1964 base year. Conversion to the wholesale level was accomplished by adjusting the constant term by the quantity effect as-

* Contribution No. 457, Kansas Agricultural Experiment Station. Missouri Agricultural Experiment Station Paper 6086. We are indebted to the Journal reviewers and editors for valuable comments and suggestions on an earlier draft.

LARRY N. LANGEMEIER *is assistant professor of agricultural economics at Kansas State University.* ROBERT M. FINLEY *is professor of agricultural economics at the University of Missouri.*

sociated with the average retail-wholesale price spread for fed beef and nonfed beef.[1] Regional demand estimates of beef consumption were based on differences in consumer disposable income and population levels. The respective regional total beef demands were:

$$G_i(f_i) = DM_i = G_i(-67.26199 - 0.97266P_i^f + 0.48447P_i^n + 0.07816I_i)$$

$$G_i(n_i) = DN_i = G_i(60.09300 + 0.47995P_i^f - 0.68909P_i^n - 0.01584I_i)$$

where

f_i = per capita demand for fed beef in region i,
n_i = per capita demand for nonfed beef in region i,
DM_i = total demand for fed beed in region i,
DN_i = total demand for nonfed beef in region i,
G_i = population in region i,
P_i^f = wholesale price of fed beef in region i,
P_i^n = wholesale price of nonfed beef in region i, and
I_i = per capita disposable income in region i.

The demand constraints were:

$$\Sigma_j M_{ji} \leq DM_i$$

$$\Sigma_j N_{ji} \leq DN_i$$

$$\Sigma_j M_{ji} + \Sigma_j N_{ji} = DM_i + DN_i = B_i$$

where

$\Sigma_j M_{ji}$ = quantity of fed beef shipped from region j to region i,
$\Sigma_j N_{ji}$ = quantity of nonfed beef shipped from region j to region i,
B_i = total demand for beef in region i, and $i = 1, 2,$ ———, 20 and $j = 1, 2,$ ——20.

As income and population were constant for the year under study, the demands for fed and nonfed beef, and thus total beef, depend on wholesale market prices of fed and nonfed beef. In the model the supply of grass-fed beef plus feedlot-finished beef must satisfy the fed beef demand whereas the supply of nonfed beef—cull animals and imports—must equal the demand for nonfed beef. The equilibrium condition—model solution—is obtained when in each region the supply of beef equals the demand for beef consistent with an equilibrium set of fed and nonfed beef prices. An iterative process is required to achieve an equilibrium, which is reached when the above relationships become equalities.[2]

Most studies specify that slaughter plants exist at feedlot locations unless cattle feeding areas determine the location of slaughter facilities [9, pp. 26–28]. The trend in recent years has been one of decentralization in the location of slaughter plants. That is, plants have moved away from industrial centers and nearer to the supply of feedlot-finished cattle; in general. however, the new plants have relocated in the same region as the original facility. The recent investments in slaughter plants near feeding areas may be one of the basic determinants of cattle-feeding locations. Existence of these facilities not only lowers transportation costs to the cattle feeder; it also allows a direct outlet for his cattle either through buyers or contract feeding. Because the actual total beef slaughter capacity of each region was unknown, regional slaughter capacity rates were estimated. Capacity of fed beef slaughter was computed as a residual, using actual total slaughter rates and assuming that beef other than feedlot fed is slaughtered within the region of production.[3]

[1] The same procedure was used by King and Schrader [3, 6, 7] to convert a retail total beef demand equation to regional beef demand estimates at the wholesale level.

[2] The procedure used in revising fed and nonfed prices and quantities in successive iterations of the problem was similar to that used by Judge and Wallace [2] to obtain equilibrium regional price differentials, except that both fed and nonfed beef prices were revised until an equilibrium was reached.

[3] This assumption does not differ greatly from actual practice, since high transportation costs of live animals usually prevent transporting low-grade beef cattle and cull animals for long distances. Thus, the regional slaughter capacity for feedlot beef was equal to the total number of beef slaughtered in a region minus the nonfed and grass-fed beef slaughtered in that region. The above figure was converted to a liveweight basis by assuming that the weight of feedlot-finished beef in each region equaled the national average of 1,065 pounds. Conversion of live weight to carcass weight was accomplished by using a dressing percentage of 58. Since five regions had negative slaughtering capacity, these regions were set at zero and the remaining regional capacities adjusted. The total fed beef slaughter capacity estimated by the above procedure was 10,406 million pounds. In the model, slaughter capacity constraints were formulated so that production of feedlot-finished beef was equal to or greater than capacity. In other words, each region's capacity had to be fulfilled by the feedlot beef produced ln that region and/or by the cattle supplied from another region. Since total production of fed beef is unknown until the results of the model are obtained, total slaughter capacity was adjusted to offset the possibility of the model deterioration. The effect of this adjustment was known, since regional capacity remains the same on a relative basis.

Table 1. Notation used in the two-region example of the spatial equilibrium model

Item	Intermediate factors					Carcass beef		
	Feeder cattle	Concentrate	Roughage	Slaughter cattle	Slaughter capacity	Fed	Nonfed	Total
Quantity available in region i	F_i	C_i	R_i		S_i	M_i	N_i	
Quantity produced in region i				$(M_i')^*$		M_i		
Quantity used or demanded in i	F^i	C^i	R^i			DM_i	DN_i	B_i
Quantity shipped from i to j	F_{ij}	C_{ij}	R_{ij}	S_{ij}		M_{ij}	N_{ij}	$M_{ij}+N_{ij}$
Transportation costs per unit	T_{ij}^f	T_{ij}^c	T_{ij}^r	T_{ij}^s		T_{ij}^f	T_{ij**}^n	
Price to feeder for carcass beef in region i shipped to region j						P_{ij**}^f	p_{ij}^n	

* Feedlot-finished cattle are expressed in 1,000 pounds of carcass beef or the equivalent of 1,827 pounds of live cattle.
** Prices for carcass beef are net prices, and therefore:
$P_{ij}^f = P_j^f - T_{ij}^f$ where P_j^f is the wholesale price of fed carcass beef in region j.
$P_{ij}^n = P_j^n - T_{ij}^n$ where P_j^n is the wholesale price of nonfed carcass beef in region j, where
$T_{ij}^f = T_{ij}^n$.

The major determinants of location considered in the model, other than regional demands for fed and nonfed beef and regional slaughter capacity, were (1) transfer cost of slaughter cattle, carcass beef, and production inputs of roughages, concentrates, and feeder cattle; (2) feed conversion by region; and (3) regional supplies of production inputs of roughages, concentrates and feeder cattle.[4]

Feed efficiency rates were developed from data reported by states on total pounds of beef production and total amount of concentrates, roughages, and silage fed [8]. To achieve a greater degree of accuracy the total amount of concentrates fed in each region was divided into various feeds in accordance with the proportion a specific feed was to that region's total regional production of concentrates. The regional supply of concentrates, roughages, and silage fed was converted to a net energy basis; and an index of therms per pound of gain was computed. These indexes were then adjusted to an index of one to obtain the regional feeding efficiency rates, which were used to adjust the rate of gains of feedlot cattle in determining the regional factor requirements for the cattle production activities used in the model.

Nonfed beef was defined as the total supply of cull dairy and beef cows, cull dairy and beef heifers, bulls, and imports of carcass beef. Grass-fed beef was composed of steers and heifers that are fattened on grass but are not entered into feedlots. The total number of nonfed and grass-fed cattle slaughtered equaled the total number of cattle slaughtered in 1964 minus the number of feedlot-finished cattle marketed. Federal marketing statistics were used to divide the total number of nonfed and grass-fed cattle slaughtered into various classes of cattle —cull dairy cows and heifers, cull beef cows and heifers, bulls, and steers and heifers not feedlot-finished. Factors were then calculated by using the total of each class of cattle slaughtered in proportion to national inventory numbers; and these factors were applied to regional January 1 inventory numbers as a basis for obtaining the regional estimates of the number of nonfed and grass-fed cattle slaughtered. These regional values were converted to a liveweight basis by assuming that the weight of each class of cattle in each region equaled the national average for that class. Regional estimates of predetermined nonfed and grass-fed carcass beef were obtained by converting live weight to carcass weight by using dressing percentage of 55.5 and 58.0 for nonfed and grass-fed cattle, respectively.

The mathematical notation shown in Table 1 is the basis for the formulation of the simple two-region example of the spatial equilibrium model in Table 2. The supply of factors available to a region for cattle feeding depends on the regional supply and factor shipments. Shipments of beef are constrained by the amount available plus the amount of beef produced by the production activities. Slaughter cattle shipments are constrained by regional slaughter capacity. The equilibrium condition exists when the factor-product allocation cannot be changed without reducing the return to factor owners and when each of the separate beef markets is in equilibrium.

Necessarily, the model analyzed was static. Perfect competition was assumed to exist on

[4] Procedures used to formulate these were essentially the same as those used by King and Schrader.

[a] The factor requirements for beef feeding activities are denoted as F_{iA}, C_{iA}, and R_{iA} for ration A (F_{iB}, C_{iB}, and R_{iB} for ration B) for feeder cattle, concentrates, and roughages, respectively. These factor requirements are denoted as F^i, C^i, and R^i in Table 1. The appropriate nonfeed cost (L_i—) associated with each production activity appears in the objective function.

both sides of the market, with the United States divided into 20 regions (Figure 1).

Feeder cattle, concentrates, and roughages were not explicitly priced in the model. The number of feedlot-finished cattle is great enough to exert influence on the factor prices in the various regions. If the present location of cattle feeding is nonoptimum, the actual prices of factors will be nonoptimum; therefore, use of the factor prices would create an influence on the results that would not necessarily be optimum. Hence the number of cattle fed in a region is determined simultaneously in the equilibrium flow of factors. The cost of feeding in a region is derived in the model rather than determined by existing costs.

Analysis of Optimal Solutions

In Table 3, the location of cattle feeding in 1964 is compared with Model A, in which allowances were made for a split demand and for slaughter capacity, and with Model B, in which

Source: Actual number of fed cattle, [9].

only the split-demand assumption was used.

In Model A, cattle feeding was specified in all but five regions and four of these were primarily in the South. The location efficiency measure[5] of cattle feeding was .78, suggesting that the adjustments necessary to achieve equilibrium in the beef sector are not large. The largest discrepancy between optimum and actual location of cattle feeding was centered in the nonfeeding regions of the South and Northwest (regions 1, 15, 17, 19, 20). Principal disadvantage of those regions appear to be lack of concentrates and/or roughages, as well as low slaughter capacities, which discourage cattle feeding. However, these five regions actually fed only about 6 percent of the cattle in 1964 and hence were not important cattle-feeding regions. Greatest regional variance between

[5] The measure used to determine the efficiency of regional distribution was developed by Henderson [1]:

$$\frac{\text{Total efficient output} - \dfrac{\text{Misallocated output}}{2}}{\text{Total efficient output}}$$

where misallocated output was defined as the sum of the absolute deviations of the actual from the estimated.

Table 4. Comparison of cattle marketings by areas for 1964, 1968: Model A, and Model B

Area	Percent of total fed cattle			
	Actual 1964	Actual 1968	Model A	Model B
West	27.8	25.1	24.0	21.1
Central Plains	22.6	23.9	29.6	38.6
Southwest	7.1	10.1	8.6	10.2
Lake States	10.2	9.9	10.1	9.0
Corn Belt	27.7	27.3	27.1	20.4
South	3.6	2.9	0	0
New England	1.0	.9	.7	.7

Sources: Actual percent of total fed cattle, [9, 10].

optimal and actual marketings was only seven percentage points, occurring in the Central Plains (regions 10, 11). This variance is minor, especially when compared with results of other studies.

In Model B, cattle-feeding numbers remained the same as in Model A for only the South and New England areas, but more cattle were fed in the Central Plains and fewer in the Corn Belt and West. Only minor changes occurred in the Southwest and Lake States. The efficiency index for Model B dropped to .72, a decline from .78 for Model A, but still indicating that adjustments to achieve equilibrium are not large.

In order to compare recent trends in cattle-feeding location with optimal locations specified in Models A and B, Table 4 shows the percentage of total cattle fed in various areas for 1964, 1968, and the two models of this analysis. The direction of change from 1964 to 1968 in actual fed cattle marketings for the areas was identical with that between 1964 and the optimal cattle-feeding locations suggested by Models A and B. Although the direction of change was the same, Model B (slaughter constraints removed) had the largest discrepancy from the actual pattern of feeding location.

Summary

Several effects of the slaughter capacity and the distinct demand assumptions were apparent. First, the cattle-feeding position of those areas that currently have a large number of beef and dairy cows, that is, a large supply of predetermined nonfed beef production, was enhanced by the separation of the total demand for beef into fed and nonfed components. Second, because a region had to feed cattle and/or ship in fed carcass beef, the distinct demand assumption caused cattle feeding in each region to be more economical relative to other regions since intra-regional shipments of carcass beef had a cost advantage over interregional transfers. Third, the specification of slaughter capacity constraints in the model enhanced a region's cattle-feeding position because live cattle shipments have higher costs relative to shipments of carcass beef.

In comparison with actual feedlot locations, both models indicate some room for improvement with efficiency measures of .78 and .72; nonetheless, they were an improvement over many previous models.[6] More importantly, both models compared favorably with recent trends in the location of cattle feeding. The direction of change from 1964 to 1968 in actual fed cattle marketings for the areas was identical with that between 1964 marketings and the optimal cattle-feeding locations suggested by Models A and B (Table 4). We contend that our study is a refinement rather than a refutation of previous studies; and we emphasize that in order for models to have applied value a careful specification of basic assumptions should precede any detailed equilibrium analysis of complex industries such as beef feeding.

An additional variable that could be considered in the spatial model, to reflect the competitive forces in the beef sector, would be the subdivision of the predetermined supply of beef into three groups: grass-fed beef of high quality, nonfed beef, and functional beef. The functional supply would become variable, like feedlot cattle, in the sense that its classification as fed or nonfed beef would depend on economic conditions. If economic, these cattle can be fed a low-concentrate ration, coupled with grazing, and thus marketed at a quality comparable to grass-fed beef of high quality. If not economic to feed, this supply of cattle would revert to the nonfed beef supply.

[6] For example, in the King-Schrader studies, the location efficiency varied from .44 to .65. It should be pointed out that in one model a separation of the total demand for beef into fed and nonfed beef components was made in that the proportion of total consumption that was fed beef was the same for all regions. The proportion that was fed beef was set equal to 46 percent for each region, with no allowance being made for regional differences in population and income which influence the regional beef demands [3, pp. 388-389].

NEW ECONOMIC ROLES FOR THE RURAL ENVIRONMENT

CHAIRMAN: MICHAEL F. BREWER, RESOURCES FOR THE FUTURE, INC.

Some Key Issues and Challenges Posed by Nonagricultural Demands for Rural Environments*

RAYMOND D. VLASIN

THE ECONOMIC roles for the rural environment, or more correctly, rural environments, extend increasingly beyond the agricultural sector and agricultural demands for rural resources. Rural environments are increasingly serving diverse ends that emanate from nonagricultural sectors and demands. The early preeminence of demands on rural environments for food and fiber production has been eroded by rapidly growing demands for recreation, second homes, retirement properties, and supplies of unpolluted resources of various types. Some of these demands are familiar and long-standing while others are new and exotic. What is more, new policies and concerns are propelling us further in this direction.

The growing national and state concerns for expanding urban agglomerations and for ways to upgrade the quality of life add a new dimension. Also, at the national and state levels, we have increased concern about improving our rural-urban population balance. The broad and continued concern for enhanced rural development and for regional (multicounty) development are important added dimensions. These several factors and others add to give major potential nonagricultural demands for rural quality and rural resources.

This paper focuses first upon nonmetropolitan environments or regions and some important considerations in their definition and delineation. Then it briefly reviews past trends concerning nonagricultural demands and some effects of policies concerning urban life, rural-urban balance, and rural development. It highlights some of the resulting issues and raises some challenges for policy makers and for professional economists. It suggests to the American Economics Association and to the American Agricultural Economics Association some specific reassessments of emphases and approaches.

Rural Environments or Regions

This is the first of three papers on "New Economic Roles for Rural Environment."[1] I would be remiss if I did not set the stage by reviewing some of the important considerations in defining and identifying "rural environments." I have deliberately used the plural "environments," for my experiences in resource economies and in area and regional economic analyses and action convince me that there are in fact many distinctly different though interrelated environments within the overall category called "rural environment."[2]

I shall treat first the matter of rural environments by focusing upon "environment." It is probably an understatement to say there is confusion about the meaning of environment.

* The author gratefully acknowledges his indebtedness to L. T. Wallace for his comments on earlier drafts of this paper.

RAYMOND D. VLASIN *is assistant chancellor for community outreach and research at the University of Wisconsin-Green Bay and assistant chancellor for extension, University Extension, University of Wisconsin.*

[1] My personal preference would be to focus instead upon nonmetropolitan environments rather than upon rural environments as requested by those organizing this session.

[2] There are many organizational and operational gains from identifying and using meaningful subsets of the rural or nonmetropolitan environment for analytical and educational purposes and for other public-private actions.

Environment—what definition

The first point to be stressed is that the term environment can be and is defined differently by different persons and different professions. It is fair to say that the majority of the writers on environment today focus upon one or more *natural resource situations*, such as inland and ocean waters, air, land, forests, flora and fauna, and our fund of mineral and fuel resources. They also focus upon wilderness areas, parks, open spaces, scenic areas and vistas, and other attributes of our natural resource situations. The identification, inventory, monitoring, use, abuse, protection, and restoration of these natural resources occupy the lion's share of the environmental arena.

There are a number of others who also are concerned about the *man-made resource situations*. The environments provided by towns and cities, the factories and commercial structures, the schools, the homes, the hospitals and nursing homes, the highway and other transportation networks, and the utilities are but a few. We build and use these man-made components of the environment daily. They constitute an important part of the total environment and are intimately interrelated with the natural resource situations.

There is still a broader view of the environment. It holds that the environment of man encompasses *physical* (natural and man-made resources), *economic*, *social*, *cultural*, and *aesthetic situations* and that these are interrelated. Further, this view holds that environmental problems are truly pan-disciplinary in nature and that analyses and solutions to those problems likewise must be pan-disciplinary in character. For an environmental improvement to be effective, it likely will need to be physically possible, economically feasible, and socially and culturally acceptable.[3]

I have found this broad view of the environment and environmental problems to be both functional and meaningful for environmental education and environmental action. A new institution (which I helped to build), The University of Wisconsin-Green Bay, has designed its entire academic plan, including instruction, applied analyses, and community outreach, around this broad conception of the environment [13, pp. 89–113].

Many different environments

The second point I want to stress is that while the world is one interrelated environmental system, it is both possible and necessary to identify meaningful and workable subsets of it and to talk about the various environmental situations outside our large urban agglomerations.

One can identify different rural environments, different rural-urban environments, or different nonmetropolitan environments and focus upon the nature and extent of their differences in problems and opportunities. One can refer to these different environments as "regions" or "environmental regions."[4]

Identifying meaningful regions

A third point to stress is that in identifying an environmental region one should not stop with physical homogeneity or simply with natural resource ties. The various other ties or linkages such as economic functions, communications, recreation, transportation, and education, as well as other social and other cultural ties, are all meaningful components of an environmental region [12]. These ties do not respect physical resource boundaries. However, they are exceedingly important as one focuses upon an environment that provides a higher quality of life and particularly important when one is concerned about the alternative feasible courses of remedial or other public and private action required to provide an improved quality of life.

Identifying a region in this manner gives one a functional economic and social framework within which to attack a wide range of environmental problems. And it gives a region that has cohesiveness and strength well beyond its economic and social ties.

[3] Land or resource economists for many years have recognized the necessity for physical or engineering feasibility, economic feasibility, and institutional feasibility, the last of these encompassing laws, regulations, organizational arrangements, and other group actions in control of individual action. For examples, see works by R. Barlowe, E. Castle, J. Frey, J. Muehlbeier, R. Penn, P. Raup, R. Renne, L. Salter, A. Schmid, S. Smith, H. Steele, J. Timmons, and C. Wantrup.

[4] The regions may differ distinctly in both their natural resource and their man-made resource bases. They may also differ in their economic base, e.g., farming, forestry, and recreation. They may have similar natural resource situations but different economic roles, e.g., recreation versus retirement area. They may differ in their social and cultural base and their aesthetic attributes. They may differ greatly in their ties and orientation with urban centers or large metropolitan or megalopolitan areas.

Importance of regions

As a fourth point, a region or regional setting is indispensable for environmental analyses and development of strategies for public action. It is clearly useful in analyzing the nature and strength of current nonagricultural demands for rural resources and rural quality. National perspectives simply do not convey the nature, magnitude, or urgency of such demands in regional settings. Regional approaches also are useful in making manageable predictions of future trends in nonagricultural demands for rural resources and rural quality and are clearly indispensable in creating plans and priorities for meeting these nonagricultural demands.

Federal and state laws and regulations now place emphasis upon the identification and use of regions for planning and developmental purposes. Further, my own research and that of fellow economists [3] indicate that a number of opportunities for simultaneously achieving economic improvement and environmental quality improvement are lost unless these are analyzed at the regional level as well as locally and nationally.

Emerging role of multicounty region

Colleagues of mine in government, industry, and colleges and universities are finding more and more that the meaningful subsets for environmental quality analyses, improvement, maintenance, and other actions are multicounty in nature. Such units usually have an urban center or centers and are comprised of many municipalities and small governmental entities. They cover various geographic configurations and do not respect state boundaries.

We have in the past year created in Wisconsin eight multicounty administrative districts.[5] They range in size from 7 to 11 counties and provide a regional framework for analysis and development of strategies covering both natural and man-made resources, as well as other economic, social, and cultural ties and features that affect the quality of human life [12].

I shall briefly review some trends in the nonagricultural demands for rural environments. Some demands have been for natural resources, particularly evidenced in changing land and related water use, and some for the aesthetic and rural life qualities, not necessarily reflected through physical changes in land and related water use.

[5] *Uniform System of State Districts*, Wisconsin Executive Order No. 22, Office of the Governor, August 24, 1970.

Some Trends in Nonagricultural Demands for Rural Resources

Natural resource demands

The 2.3 billion acres of land resources of the 50 states vary considerably from one part of the country to another in terrain, soil, and climatic conditions. The same can be said of the 1.9 billion acres of our 48 contiguous states. The uses and the use changes in these land resources also vary considerably.[6]

At the national level we see several major changes in land use. First, the amount of land needed to provide food, clothing, and shelter for the average American is decreasing. For example, the amount of land used for agricultural crop production has been decreasing on a nationwide basis. From 1950 to 1970 there has been an estimated net reduction of 37 million acres of cropland in the 48 contiguous states, or an average of 1.9 million acres a year. While the decrease is nationwide, the change varies by region. In some regions cropland has remained stable or has increased; in others it has clearly decreased.[7]

Second, we see a continued shift of land into nonagricultural uses, both urban and rural nonfarm. Such shifts of land to noncrop uses have been prominent in the Northeast, the Appalachian states, and the Southeastern and Southern Plains states. Some of these changes resulted from low productivity soils; from small, rough and isolated fields; and from limited moisture. Others resulted from demands for various urban and transportation uses, nonfarm residences, recreation, and other nonfarm public and private uses. These shifts have been particularly prominent along the eastern seaboard and near rapidly growing metropolitan areas elsewhere in the country.

Nationally we expect little change in the amount of grassland and pasture.[8] Forest land

[6] The Natural Resource Economics Division in the Economic Research Service of USDA continues to provide excellent statistics and evaluations on land and water resource use and change [2].

[7] During the 20 years from 1944 to 1964 about 54 million acres in some regions were changed to noncrop uses, while some 27 million acres of new land in other regions were changed to crop use. Cropland accounts for 23 percent of our land resources.

[8] Grassland and pasture ranges occupy about one-third of the area in the 48 states and is expected to continue at about that level through 1980 [2, p. 208].

and woodlands have increased slightly over recent decades. The acreage is projected to increase only slightly during the next decade.[9] Substantial acreages of noncommercial forests in the West and Southwest have been cleared or reclassified to other uses. Acreages of commercial forests have increased in the South and East.

Third, even though the national trends in net land use changes seem slight or moderate, they mask major changes occurring in small multicounty regions.[10] One need only visit from time to time the areas adjacent to Baltimore, Washington, Chicago, Minneapolis, Denver, and the San Francisco Bay area to see the enormity of changes in the counties adjacent to them. Or in my own state, Wisconsin, one can see major land use changes in Southeast Wisconsin near Milwaukee, in Southern Wisconsin near Madison, and in Northeast Wisconsin near the Fox River Valley cities and Green Bay.

Fourth, besides the shift of land to intensive urban uses, there has been a shift of land to extensive nonagricultural uses as well. The increasing demand for parks, recreation areas, wildlife areas, and other public areas and facilities is causing land use shifts to these uses. Together the land use shifts for these intensive and extensive uses are projected to be 14 million in this decade, or about one and one-half million acres per year.[11] Again, one must be aware that the shifts within a multicounty region can be major. That national figures show that we have land in the aggregate for all our domestic needs is of little consequence to small multicounty regions that are experiencing major land use changes which governmental units cannot adequately plan or guide.

Fifth, as we look at the new products and new services demanded in nonmetropolitan areas, we see only part of this demand reflected in statistics of land use changes. All manner of residential sites are being demanded, extending from opportunities for dense residential development near an urban center to scattered residential use, full-time and part-time, at great distances from urban centers. All manner of residential-recreational sites are being demanded, ranging from a lovely home on a lake, seashore, or scenic overlook to the most primitive cottage or place to pitch one's tent or park one's camper during the summer or other seasons. Near urbanizing areas all manner of business, commercial, industrial, and service facility sites are being demanded, including places for shopping centers, processing and manufacturing plants and parking areas, storage and distribution facilities and terminals, schools and playgrounds, police and fire stations, hospitals and clinics, and service centers for other public and private services. All manner of public recreation facilities and services are being demanded, ranging from large multiple purpose parks and forests to more specialized facilities such as playgrounds, beaches, public lakes and streams, wildlife refuges and areas, wilderness areas, scenic highways and trails, scenic overlooks, public campgrounds, and picnic areas. All manner of private recreation facilities and services also are being demanded for fishing, hunting, swimming, camping, hiking, horseback riding, skiing, picnicking, skating, relaxing in privacy, or enioying a vacation on a farm. Also being demanded are sites for our improved transportation networks; namely, the interstate and state trunk highways, the service plazas, the automobile and truck terminals, the motel and restaurant services, as well as the new and expanded air terminals and supporting services.

It may sound to you as if I have enumerated every possible demand in sight. Quite the contrary, this is but a part of the array of old and new products and services being demanded in our nonmetropolitan areas.

Notice that I have said nothing about the array of demands placed upon nonmetropolitan areas to receive the enormous waste created in metropolitan areas. These wastes are equivalent to the total input of goods going into the metropolitan areas and come forth as solid, liquid or airborne wastes [4, p. 8].

One could also focus upon the water supply [9] and show how the nonmetropolitan area has had to meet increasing demands from the metropolitan areas. Many of the demands for sites and services discussed above are in fact demands for land and associated water. The

---

[9] Forest land and woodlands occupy slightly more than 30 percent of our land area in the 48 states. Regional shifts have been significant [2, p. 208].

[10] The shift of land into intensive urban uses has been increasing gradually, with about 3 percent of our land now devoted to intensive urban and transportation uses. About 58 million acres are now in intensive urban and transportation uses, and the amount will probably reach 65 million acres by 1980 [2, p. 208].

[11] About 85 million acres are presently in these extensive special uses, projected to be 92 million acres by 1980 [2, p. 208].

examples would differ in some instances, e.g., water for hydroelectric power, waste dilution, navigation, habitat for fish and wildlife, water-based recreation, municipal water supplies, industrial processing, and nuclear generating plant cooling.

Since the United States population is expected to increase about 15 percent by 1980 and may increase as much as 50 to 100 million people by the year 2000, we can be absolutely certain that the amount of resources demanded will also increase. Since there is every indication that the population increases will concentrate in the metropolitan and megalopolitan areas, this increased demand will have its origin in the metropolitan areas and will have its impact in the nonmetropolitan areas, namely ,the rural environments. In short, more people will demand more resources, And, if real income per capita increases as expected, if leisure time and mobility increase as well, and if more and more families adopt life styles that include a second and third home and new undreamed of conveniences, our shifting demands for resources will be even more accentuated.

As Marion Clawson of RFF points out, there also are some counterforces that serve to diminish the need for natural resources, at least relative to the growth in GNP: (1) Increasingly our total national output is made up of services of many kinds, rather than goods; (2) the efficiency of natural resource use has risen; (3) the average unit of natural resources is processed today to a far greater degree than a generation ago. While these counterforces will continue, they will temper but not offset the increased demand resulting from our growing population, higher per capita real incomes, and more consumptive life styles [1 pp. 338–339].

Dr. Clawson and his colleagues conclude that for the foreseeable future the material well-being of the American people will not be jeopardized by absolute scarcities or seriously rising prices of raw materials. They point out, as I have earlier, that there will be problems of providing enough natural resources of the kinds sought, in the time and place demanded, at what seem to be reasonable prices [1, p. 339].

Demands for quality

More serious, however, will be the demands for quality in the available natural resources. It appears that people are going to demand higher quality in their available natural resources. Nonmetropolitan areas are going to be asked, or demanded, to provide water for recreation that is less contaminated, runoff that is less polluted, air that is less befouled, parks that are less littered, roadways that are less cluttered, lakeshores that are less unsightly, forest areas that do not show the scars of clear cutting; and wilderness areas that are protected from overuse.

The same beliefs and values that give us growing population and a desire for more conveniences, comforts, and consumption, or more and better quality goods and services simultaneously give us more waste residuals that take the forms of air, water, or solid wastes. The wastes must be absorbed, and in large measure in the nonmetropolitan areas.

The rural environments must now also provide opportunities for social, cultural, aesthetic, educational, and scientific enrichment of our urban populace as well. Rather than giving you hypothetical examples, I have gleaned the following actual examples from the local news media during a one-month period: Use of 1,400 acres of county forest for scientific purposes, to determine the effects of nuclear gamma rays on trees and plant life; demands for preservation of the lands and cultural heritage of Menominee County for the Menominee Indians and others; proposal for a residential-recreation complex for special recreation, aesthetics, and social benefits to potential occupants; demands for preservation of the scenic Wolf River in its wild state; pleas for building recreation-residential units on artificial lakes to provide a restful and aesthetic setting; demands for a new interstate highway and differences of opinion between highway engineers and ecologists over route locations; plans for possible use of geologic formations of Northern Wisconsin for a low-frequency communication system with an extensive underground antenna grid. There were of course many more articles that treated the demand for resources and resource quality in rural environments and many articles on the matter of waste residuals that must be absorbed by rural environments.

I have made the case that our nonmetropolitan areas will be required to produce a different array of outputs beyond those customarily provided by the agricultural sector. I have done this by reviewing activities with little reference to possible changes in national and state policies that bear directly upon the new roles for rural environments.

Possible Nonagricultural Demands from Emerging Policies

Policies concerning urban life and improved rural-urban balance

Various agencies and groups at the federal and state levels have become concerned with the quality of urban life, or the quality of life and living in urban areas. Early concern for the slums plus later concern for other forms of blight, crowding, noise, filth and litter, automobile and other traffic congestion, and air pollution have given rise to reassessment of some of our programs concerning urban growth. It should be clear to even the casual observer, however, that our nation and our states have lacked clear-cut policies concerning quality of urban life and the massing of people in metropolitan and megalopolitan areas.

Concern has led to a great many federal programs, in fact, to catalogs of programs for federal domestic assistance to states, communities, groups, and individuals. Concern has also led to creation of the Rural Affairs Council and the Urban Affairs Council and their subsequent consolidation into a Domestic Affairs Council at the federal level, with a keen interest in rural-urban balance.

Interest in more balanced growth to affect positively the quality of life in urban and rural areas has led to various proposed strategies or policies. One of these is to retain population in sparsely settled areas and to spread population to sparsely settled areas by generating economic growth there. A second is to deliberately foster growth of smaller cities and towns in nonmetropolitan areas, whether individually or in some grouping. A third is to create new cities outside metropolitan regions [6, pp. 39–61].

Interest in improved rural-urban balance also has given rise to new efforts by governors. In my own state it led to the creation of a Mission 70 process in the spring of 1970, an effort on the part of Governor Warren P. Knowles to bring more orderly and balanced development to Wisconsin. He and others recognized that at the same time that Wisconsin's smaller rural communities and rural areas were suffering from declining human and economic resources population growth in certain urban areas threatened to strain the resources of the cities beyond endurance [5]. Since I was a member of the statewide Mission 70 Council and chairman for a regional inquiry into problems, policies, and possible programs for the Northeast Wisconsin region, I have some first-hand observations to share with you.

This inquiry [11] disclosed that in the multicounty region of Northeast Wisconsin the most urgent problem was insufficient employment opportunities to maintain current populations and provide a viable base for improved state rural-urban balance, and the second most urgent problem was deterioration of the surrounding environment. Further, the inquiry showed that the decisions made about increased employment and the decisions made about environmental quality improvement were not interrelated, although actual effects of the two are closely interrelated.

It was clear also that some rural areas do not have the type of services and facilities needed in order to absorb increased populations and that many rural areas do not have the quality of services that their current residents require. Therefore, if a policy of improved rural-urban balance is to be pursued in Wisconsin, the nonmetropolitan regions must provide economic opportunities, an improved level of services, and a quality of environmental amenities that will attract new residents from the metropolitan areas. If a policy of improved rural-urban balance is implemented, it probably would accentuate materially the nonagricultural demands placed upon rural environments today.

Policies concerning rural development

For many years the federal, state, and county governments, as well as our land-grant colleges and their experiment stations and extension services, have fostered rural development. This continuing effort had its origin in ideas of the 1930's and received impetus in the 1950's and early 1960's from USDA's Rural Development Program and the subsequent Rural Area Development Program. Interest and activity in rural development has continued, with increased attention being given to multicounty approaches. While we have had multicounty areas for use in collecting agricultural and other statistics for many years, the use of such areas for assessing problems, identifying opportunities, and planning development activities is quite recent. The Resource Conservation and Development Districts developed under the sponsorship of USDA are prime examples of the recent efforts.

Federal and state agencies in addition to those concerned with agriculture have developed multicounty approaches to planning and action that foster rural development, Notable

among those created under federal programs are the Economic Development Districts and their counterparts in Appalachia called Local Development Districts. States also are creating uniform state administrative districts on a multicounty basis, and federal agency districts are being adjusted to become coterminous with the state districts. These and other governmental efforts are fostering rural development.

The multicounty districts for development hold some promise for enhancement of rural areas through new and better income and employment opportunities and through improved and more efficient public services. They hold promise in retarding the growth of megalopolitan and metropolitan areas as they enhance the identification and implementation of new income and service opportunities outside [3].

As rural development policies and processes are implemented, they too accentuate the nonagricultural demands placed upon rural environments today. One need only look at rural development efforts in recreation to see the array of new public and private recreation facilities and services created. These new recreation facilities and services require different uses of land, labor, capital, and management than previously required in our rural environments. Even agriculturally related businesses, such as food processing firms, result in new demands for rural resources and rural quality.

Issues and Challenges

Some key issues

A number of issues and challenges have been indicated by the trends and policies just reviewed. Here are a few of the issues.

First, we observed that the rural environments will be required to produce an increasingly different array of outputs than in the past; that the output of agricultural products and services will be challenged more and more by demands for nonagricultural products and services. One of the key issues will be whether the production challenges presented by the new demands can be met. Can land, labor, and capital be mobilized to meet these new demands? Can the management and control of these resources be aided in being responsive to these new demands?

Second, the quality requirements of the new and growing demands are inconsistent with the increased quantity of physical resources required by these demands. A key issue will be whether we can raise for searching reexamination and possible modification the beliefs and values about life style that include increasing population, increasing consumption, and limited concern for the side effects.

Third, these new and growing demands are a new breed. The demands for rural resources and rural quality are not necessarily contiguous to the metropolitan or megalopolitan areas from which they emanate, but can jump from a few miles to great distances. The specific demands differ widely in their predictability.[12] They are both market and nonmarket in character, and some of the most directive in terms of resource use changes are nonmarket. Further, the demands are very iffy. They are heavily contingent upon values and attitudes of people about consumption, upon population growth, and upon national and state policies and programs concerning rural-urban balance and rural development. One of the key issues here is whether we can cope analytically and operationally with the identification and prediction of these demands. A related issue is whether we can translate those predictions into meaningful plans and actions for servicing the demands.

Fourth, national and state concerns for retarding the growth of megalopolitan areas and for retaining current populations in less sparsely settled areas clearly require economic and social development of the nonmetropolitan areas. Such concerns require also a consistency of purpose in various federal and state policies and programs beyond what has been achieved in the past. One key issue here is whether we can deliberately develop in tandem policies and programs at the national and state levels with consistency of purpose in land settlement; in economic development; in environmental improvement; in transportation; in health, education and welfare; and in rural development. A related issue is whether these can be translated into meaningful substate plans that at the same time involve substate areas in decisions about their destiny.

Fifth, if nonmetropolitan areas or rural environments are to meet growing demands from urban areas and at the same time help bring about an "improved rural-urban balance," the leaders and citizens must develop some clear goals or targets. We have a massive arsenal of federal, state, and local programs and agencies

---

[12] One need only consider the difficulty in predicting demands for improved quality of water runoff, for cleaner lakes for swimming, for recreation-residential home sites on artificial lakes, and for lands for scientific use to sense the complexities involved.

and manpower for economic and social improvements. However, we are woefully lacking in visible targets. Thus, another key issue is whether we can develop functional economic and social developmental targets toward which joint public and private efforts can be efficiently directed and coordinated. While targets are needed at the various governmental levels, they are indispensable for efficient action at the multicounty level, as are professional staff,[13] funds, and analyses.[14]

Added challenges for economists and our associations

A number of challenges for economists and our associations are clearly implied in these issues and will not be repeated here. In addition. we must give much more attention to the economics of a closed environmental system and to meaningful subsystems. We should openly and widely raise and discuss the consequences of our fixation upon the amount of throughput from the factors of production to consumption —our chief measure being GNP.[15] We must evaluate the likely side effects of a larger and larger throughput on the quality and character of individual lives and its likely differential impacts on resources and regions. We must determine ways in which decisions about economic development can be integrated with decisions about environmental improvement, both in the public and in the private sectors. We must evaluate the current and emerging beliefs and values and their consequences for our future and at the same time assess credible alternative beliefs and values and their likely results. We must determine the specific amenities, qualities, and features that people prefer in large urban areas and sparsely settled rural areas and ways of providing these at different population sizes and configurations [8]. We must become more deeply involved in identifying possible economic and social development targets at the multicounty regional level and must design economic and social indicators to improve public and private decision making about targets and progress toward them [7, 10].

Neither economists nor associations can remain simply with their "own kind" and expect to make major impacts on any of these problems. Concerns for rural environments, rural-urban balance, urban and rural amenities, consequences of beliefs and values, economic and social development targets, design of economic and social indicators, and other matters go well beyond economics. The problems are pan-disciplinary in nature, and analyses related to them must also be pan-disciplinary to be thorough. Thus, the economist must deliberately identify problems and design and conduct analyses with members of other disciplines. The economist must also involve those leaders who are confronted with decisions about the rural environments. If we are to contribute something truly meaningful, the walls surrounding our economics and agricultural economics disciplines must come down. If we are to make contributions that are indeed used, walls between the professional economist and decision makers in our communities and regions must come down too.

[13] Not only will the nonagricultural demands confronting a multicounty region differ, as will the economic and social development possibilities, but the region's professional and financial capabilities for planning and action will differ also. Another important issue is whether federal and state governments will provide the technical and financial resources needed to permit these multicounty units to organize, staff, conduct ongoing analyses, develop and update plans, and monitor progress and effectiveness. The Bureau of the Budget directives that specified creation of regional clearinghouses to evaluate federal grant, aid, and loan proposals did not provide a procedure for staffing and financing those clearinghouses.

[14] A colleague, James Murray, is estimating possible per unit cost savings for public services that might be achieved by rural counties and communities through increased population size. Such analyses are fundamental to estimation of current economic benefits that can accrue to the public sector from the addition of population to some less-populated areas.

[15] Even the use of the measure needs a searching re-examination. For example, we have adjusted GNP to measure its growth without inflation. We have adjusted GNP to show it has not grown at the rate it could have, yielding a GNP gap. However, we have not evaluated GNP and its side effects to show the disinvestment in the resource base resulting from different levels and compositions of GNP.

Future Use of Rural Resources*

L. T. Wallace

WHAT DO THE emerging patterns of U. S. production and consumption imply for the use and management of rural resources? To what signals should rural resource allocation decision makers respond? Increased population, the broadening demands of an affluent citizenry, reduced time constraints, extended possibilities for factor substitution, and ever closer ties between urban and rural interests have intensified pressures on rural resources for other than agricultural use. Increasingly, contemporary life styles entail increases in the demand for rural amenities, a desire to modify production processes in order to sustain or "renew" a high-quality natural environment, and a concern that those with low incomes not be denied access to a reasonable quality of life.

Many people, concerned about the nation's productive processes and their impact on the physical and social environment, have involved themselves in transforming rural resources. While we do not yet know the full dimensions of this transformation, it is clear that comparing values determined by capitalized product and factor rents, annual income streams, and imperfectly competitive governmental resource use permits is no longer a theoretically unassailable way for determining what use of a resource yields the "highest and best use."

Preservation and conservation interests are challenging with increasing success the underlying logic by which rural resources have been organized only for food and fiber production. Absolute increases in demands for extractive commodities (food, fiber, minerals, lumber, etc.) vie for rural resources with increases in demands for nonextractive uses. National agricultural policy finds increasing fragmentation within the organized agricultural interest groups. Rural development, while an agenda item of most domestic departments of the Federal Government, still has trouble identifying the critical issues in the population-resource balance of rural communities to permit rational regional economic development efforts.

Economic, social, and political dynamics strongly suggest that the ground rules for using rural resources in the future will be different. The profession of agricultural economics has an opportunity to help clarify these rules and to develop new criteria for public policy pertaining to rural resource use.

New Patterns of Rural Resource Use

There is substantial evidence that both absolute and relative shifts have occurred in the demand for rural sector goods and services. Transportation has reduced the time factor bringing all nonmetropolitan areas closer to urban centers; employment opportunities creep outward into urban centers and satellites; land development leap-frogs in an effort to bring cheap housing and recreation to employees located in urban centers; and ultimately, the areas closest to population concentrations get swallowed (albeit under conditions of economic rationality) and become launching pads for increased "opportunities" for development.

The size and form of population concentration helps to explain part of the rural resource pressures. Rapid urbanization is the dominant trend. From 1960 to 1970 the population in nonmetropolitan areas grew about 4.6 percent compared to about 18 percent for metropolitan areas [5]. The merging of metropolitan areas allows no relief from urban resource use intensity and results in scale problems of waste management. With over 70 percent of our population concentrated on slightly over one percent of our land, it seems inevitable that sheer quantity of use cannot hope to maintain the original threshold of resource quality. It also seems inevitable that with deteriorating quality of urban resources, rejuvenation is sought in outlying areas.

Some rural counties have sustained several decades of persistent outmigration. About 1,500, or half of the counties had fewer people in 1970 than in 1960. Farm population dropped about one-third, or about 4.5 million people, during the 1960's [1]. Nonfarm people in non-

* Giannini Foundation Paper 315. My thanks to Michael F. Brewer, without whom this paper would not have been started, for his strong editing suggestions, and to Ray Vlasin and Lynn Daft for their most helpful comments.

L. T. Wallace *is an economist with the California Agricultural Extension Service and on the Giannini Foundation of Agricultural Economics, University of California, Berkeley.*

metropolitan areas increased about 16 percent or about seven million people, in the same period. The growth in nonfarm nonmetropolitan population plus persistent outmigration data from agricultural and mining counties suggest expanding rings of population surrounding the goods and services employment-rich metropolitan centers [2].

Urban-to-rural migration is another factor in the growth of the nonmetropolitan rings surrounding metropolitan areas. Almost a quarter of the "ring" residents were of urban childhood origin [1]. This group has a lower poverty incidence than the rural people, more sophisticated jobs, and a higher educational attainment level [4]. However, by and large, nonmetropolitan areas still have lower per capita incomes than the metropolitan areas, less education, fewer services, and fewer cultural attractions [8, 7].

Since 1950 population has increased 34 percent; but electric energy production has increased 300 percent, natural gas usage has risen about 250 percent, crude petroleum usage is up about 100 percent, and the number of cars and trucks has more than doubled [1]. Our standard of living has enabled us to consume more resources at a faster rate than ever before. It seems quite natural that some people are asking: Consumption for what ends? Can our society slow resource use and maintain itself? What are the current and predicted relationships between growth, stability, consumption and equity? How can coordination between uniquely endowed regions be accomplished?

While the relationships among demand shifts, production activities, social welfare, and resource allocation operate reasonably well within appropriately competitive product and factor markets, there are good reasons for expecting that current demand dynamics for rural resources will not be translated into socially efficient allocation patterns without some policy intervention. These reasons include: (a) difficulty in specifying the social demand or utility functions; (b) poorly understood technologies for producing certain types of rural services; (c) obscurity of the total costs of production; (d) institutional obstacles to human mobility; (e) policy constraints upon production possibilities. Each of these is discussed briefly.

Specifying relevant demand functions

There are many reasons for confusion about the signals to which organized rural sector production activities respond. First is the question of what is really being demanded. We used to know, intuitively at least, what rural community utility functions were and how to maximize them. Now the population pressures and other factors mentioned above have extended the conventional parameters. This is especially true considering the increasing national sensitivity to the aesthetic and other qualitative dimensions of rural resources.

However, demand functions presumably measure willingness and ability to pay for what is wanted. While it may be possible to estimate demand functions for different recreational environmental qualities (i.e., demand functions for different recreational environments may be synthesized from visitor-participation data), what is a community's "willingness to pay" to obtain a certain level of dissolved oxygen in its rivers and streams as opposed to some lower level?

A related problem that obscures allocation signals is the lack of traditional markets for many of the new environmental services desired from the rural sector. As a consequence, we do not have explicit information about quantities transacted at different price levels. The possibility exists that a current market price efficient decision can quickly become inefficient if a time lag is encountered in the adoption of technology or institutional persuasiveness, if social values change, or if new knowledge is provided. Current market price decisions perhaps favor short-run extractive industry interests more than the preservationist point of view. It might be difficult not to get frozen into an untenable resource use situation on the basis of incompletely revealed preferences or poorly defined shadow pricing.

The importance of collective goods and services in the rural sector raises additional problems relating to specifying demands for rural resources. From the standpoint of an individual, environmental quality or its lack is characterized by economic externalities. Partially in response to this the unit purchasing the bulk of these goods and services has tended to be governmental, a county, state, or region. The problem of efficiently encompassing individual preferences into some form of community demand function thus becomes extremely important, if we are to discover what communities really are willing to pay for these qualitative goods and services. Some mechanism that provides information about production possibili-

ties and permits trade-offs among individuals with different value rankings becomes an important ingredient for actually articulating demand. If the growing national interest in the amenities of the rural environment truly reflects a willingness to pay, this area warrants high priority research efforts.

Poorly understood production technologies

While the production technologies of food and fiber are relatively well understood, we appear to have few equivalent resource-response data regarding the production of amenity goods and services derived from rural resources. For example, we have been operating largely on the assumption that a recreational enterprise simply provides a number of fundamental facilities, such as access, parking, and sanitary facilities, at not "too high a price." As recreational consumers have become more articulate, a demand has emerged for different types of recreational opportunity which often are mutually exclusive. Yet our notions about alternative ways of producing these services are as primitive as our notions about "maintaining the quality of our environment." For example, is a wilderness experience identified only by low density of use; are there land management programs capable of producing a "real" wilderness experience (or one that has sufficiently high "quality" to satisfy the demands of a particular wilderness constituency)?

Another example: What are the land management measures for scenic highways which must complement the structural engineering to produce the desired "product" (assuming the highway should be built at all)? In mountainous areas, are all timber harvesting measures to be ruled out, should timber be clear cut to offer "enhanced viewpoints," or should some compromise growth-harvest-view policies be determined? The cost of road investments and the willingness of private landowners to participate will be highly sensitive to the answer.

As the rural areas of the United States are increasingly sought for residential or second-home purposes, the production functions (as well as the goals) for community and social services become increasingly important, multivariate, and complex. History has provided us much empirical information regarding services such as water supply, sewerage, and electricity; however, often these supply systems were organized for relatively small, year-round agricultural communities and did not take full advantage of contemporary production techniques. With increasing recognition that some of the older patterns of rural area settlement are cost inefficient, new production techniques become extremely important. Indeed, what economies of scale considerations in providing public services should be taken into account when determining the population settlement patterns we wish for the future, as well as the organization and financing of local governments once established?

The obscurity of production cost

A third reason why the evolving array of demand on rural sector resources is not automatically translated into efficient allocation patterns is that the full costs of production activities often are not incident upon the entrepreneur. Much has been made of the external costs imposed by the leftovers or residuals from extractive production activities. To these concealed and sometimes publicly subsidized "costs of production," should be added similarly subsidized "costs of consumption" when residual energy and materials from consumption must be disposed of into the environment. Under current policies and procedures, when these externalities costs are not borne by the producer or immediate consumer, relevant prices and costs may not be used when performing conventional economic analyses of calculating contract isoclines, cost and revenue curves, values of marginal products, opportunity costs, and other benefits and costs.

Failure to account for full production costs often introduces a systematic bias in rural resource allocation decisions. This is especially liable to occur between extractive uses and preservation uses. Usually preservation uses have few if any external costs, while those of extractive activities can be substantial. One hopes, as environmental protection policies are introduced to internalize these external costs, that efficient allocation decisions will result. It is an open question whether one can clearly count on the enactment of such policies or whether specific policies for rural resource allocation should be introduced that compensate for the biases of today's private enterprise bargaining process.

Obstacles to factor and human mobility

Fixity of capital discourages factor mobility and thereby directly reduces medium- to long-run efficiencies of resource allocation. Yet many

current programs, such as Farmer's Home Administration water and sewer grants, encourage indiscriminate fixity of social overhead capital in communities where, despite subsidies, per capita costs of public services remain high, services continue on a limited scale, and quality of service often remains low.

Future capital needs may be toward greater liquidity concentrated within a specific geographic area. People deciding this capital allocation must confront the political unpleasantness that all geographic areas need not be treated equally by public agencies, since differing resource endowments entail differing marginal social products and payoffs.

One question we must face is whether, with limited national resources, all of the country's villages, towns, and cities have equal right to call on the nation's budget without some corresponding move towards establishing a more economically viable concentration of people. Perhaps it would be kinder in the long run to let some communities die while others are encouraged to grow, subsidizing the move for residents who want to move to places of agreed-on population concentration.

In essence the population problem is also a job location problem, affected by all of the economic and noneconomic factors that affect industrial and service employment. Overall policies providing access to education, housing credit, and transportation considerations may be first priority "enabling employment" tools, but they are seldom "job providing." Employment opportunities still seem to follow the rule that the richest areas get richer, a pattern that has not changed much during the last decade despite efforts to alter it.

Poverty includes more people in rural areas than in the urban areas, and because of its relatively high rural incidence there is need for certain services to be provided outside of regular market channels [4, 6, 7]. The infrastructure of state services must be relevant to the current needs of people. For example, job information could be circulated within a region and job applications solicited without causing the job hunter to take a long and sometimes expensive trip to no avail. Use of computer facilities could quicken the screening of applicants and hasten job notification in much the same way airlines now check for available seating at time of reservation.

Perhaps the concept of "bundle of rights" associated with proprietary interests and the control of rural resources might also be reexamined with a view to possibly separating certain of the property rights from the bundle. The rationing of rural resources or access to them and progressive price discrimination by public agencies are policy alternatives to fee simple purchase for achieving changes in real income distribution which directly challenge the ownership thesis of the bundle. Master plans and zoning ordinances have been proven time and again to be ineffective and weak public servants when opposed by a determined developer. When the community utility function in rural areas was perhaps more homogeneous and intuitively better understood thirty to fifty years ago than it is now, factor weights and values were well accepted in fairly evident production and consumption functions. However, with changing technology, evolving demands, and changing social values, a critical review of the proprietary aspects of rural resources would not seem inappropriate.

Constraints on policy alternatives

It is always difficult to identify and choose which policy or set of policies is most appropriate in a situation characterized by flux. Organizational-institutional arrangements for implementing and adjusting to changes in the evolving production-consumption mix bearing on rural resources have become increasingly complex. It is clear that we have not fully explored the jointly responsible ranges of complementarity between state, regional and local, public and private, controlling entities. However, the advent of more federal-state revenue sharing may permit experimental joint ventures with regional governances for the sake of efficient project conception and implementation.

Decisions concerning resources in nonmetropolitan areas are becoming dominated by metropolitan dwellers. Open space, recreation access, second home sites, green belt zoning, highway construction, and lack of explicit tax relief for rural resource owners are topics lending themselves to this domination. On the other hand, rural institutions often favor agriculture to the exclusion of multiple use concepts. Farmers, as price takers, feel thwarted when their resource control and incomes are threatened in the name of quality of environment, ecology, and equity by city residents who are independent of rural resources for their livelihood.

Local governance in rural areas sometimes is

unable to reconcile these conflicting viewpoints and institutional fragmentation. Preservation and enhancement of amenity resources meets head-on the need to create jobs and living spaces. Pressures from technology, from transportation, from international markets, from the factors affecting effective final demand, and from the derived demands for production and service inputs have put intensified pressures on all levels of institutional decision making.

While common themes run from federal to regional to local bodies or agencies of government, under our present social-political-economic system direct initiative control of resources at the community level is limited [3]. Primarily, one sees there a response to specific federal or state legislation. The continuum reduces degrees of freedom as the channel is traced from federal conception to regional and thence to community implementation. While much enabling legislation comes "down the Pike," its effectiveness is dependent on local initiative, interpretation, and understanding. This situation allows for urban suggestion, regional obstacles and hesitation, and rural enactment, with a resulting overview of confusion, lack of any goal attainment, and wasted resources.

An Applied Research Effort

Many California counties are on the fringe of rapidly urbanizing areas and are subject to increasing development pressures. Some county officials have been concerned about what "agriculture" is worth to their economy. Using input-output technique and both primary and secondary data, conservative estimates were obtained for ten agricultural sectors and nine other sectors.[1] These estimates provided a chance to evaluate several resource use options, thereby offering an educational opportunity for Extension personnel, county officials and interested citizens to discuss which course of action might be "best." A secondary educational objective was to provide county officials with the input-output tool (programs, data cards, etc.) using economists at the University for interpretation and help in determining resource policy.

A five-county region was defined north of the Bay Area and a separate set of tables constructed for each county. The first step was to estimate the basic dollar flow or transaction table, the technical coefficients table, and the inverse matrix for 1965. The second step was to make projections of these tables for a reasonable planning period of twenty years. The third step was to estimate the economic effects of selected but pertinent resource changes within the county.

In one county four simplified examples of different ways to use the county's resources were used to illustrate input-output as an aid to decision making. Each example was based on an actual unresolved resource use question in the county. The first example called for an estimate of the initial economic effects on the county's economy of a 20 percent decrease in the county's timber production due to fire; the second was to estimate the economic effects of planting 5,000 acres of wine grapes; the third was to estimate what the loss to the county would be of closing down the county-state hospital; and the fourth estimated the gross economic effects of establishing a 1,100-student junior college in the county.

The timber production loss amounted to a sales decrease of $8 million, expanding into a gross economic loss to the county of slightly over $22.5 million. Put another way, for every dollar of sales decrease the county lost an additional $1.81 of economic activity.

In order to plant 5,000 acres of wine grapes, 5,000 acres of hay had to come out of production. Annual sales attributable to the wine grapes were estimated at just over $1.5 million and resulted in a total increased economic activity of about $3.5 million. However, when the economic effect of the withdrawal of hay acreage was subtracted, the net effect of the wine grapes on the county's economy was about $2.8 million.

The budget for the hospital was about $12.4 million. An additional two dollars was generated for every dollar of expenditure, so that the total loss to the county if the hospital were to vanish was around $36.5 million. In part this estimate is so high because approximately 80 percent of the hospital budget is spent on salaries and wages that are consumed locally.

Data for the junior college example were taken from an operating budget ($1.2 million) of a similar school. Estimates were made of in-county and out-of-county students, whether they would room at school, and how much they might spend. When the effect of the college's

[1] At this time the preliminary manuscripts are being revised. More complete information will be published in the spring or fall of 1971.

operating budget ($3 million) is added to the effect of the student's expenditures ($2 million), the total gross effect in additional sales amounts to just over $5 million.

While the examples used were only estimates, the analyses were timely and provided local officials responsible for making decisions about land use, health facilities, and schools with quantitative resource information they had not had before. While much can be done to improve and modify the estimates, much has been gained too, since many county residents participated in gathering data which they considered to be important and in rendering judgments about them.

One important thing derived from this research-education effort was an analytical framework that local decision makers could use because it was both problem- and location-specific to them. The audience was ready. The need to study resource problems other than those concerned solely with commercial agriculture is evident. As economists, we can do much to help evaluate future rural resource development and use by offering timely and sometimes "imperfect" analytical information to private and public groups interested in enhancing nonmetropolitan America.

Public Policies for Rural America: Legacies or Leading Edges?*

LYNN M. DAFT

THE AIMS of this paper are three-fold: first, to identify and briefly evaluate the performance of some major public programs having impact on what is generally considered rural America; then, to examine some of the key forces behind this performance; finally, to consider some implications for future policy making.

Programs and Performance

For the purposes of this paper I find it convenient to think in terms of three types of programs: (1) those that are specifically directed toward rural issues; (2) those that are essentially rural in character but are not explicitly limited to the rural setting; and (3) programs that have no particular geographic focus but have impacted in varying degrees on the rural population.

A large share of the public programs that relate most directly to rural people address needs of the agricultural sector. Many were enacted during an era in which the agricultural economy was depressed or threatening to become so. Agriculture and rural were nearly synonymous. In the early 1930's a large share of the total rural population was engaged in farming. Most of the remainder were indirectly linked to agriculture through employment in farm service, supply, and marketing activities. It is also noteworthy that responsibility for implementing a majority of these programs was lodged in a single federal agency, the U.S. Department of Agriculture.

In more recent years nonagricultural needs of rural areas have begun to attract the attention of public policy makers. Though these programs have not been limited exclusively to rural areas, their expenditures have been proportionately greater there as a result of program design. This list includes the Economic Development Administration projects; the Appalachian Regional Commission; Hill-Burton hospitals; the housing, water, and sewer programs of the Farmers Home Administration; the Department of Housing and Urban Development's nonmetropolitan comprehensive planning program; Corps of Engineers projects; the rural loan programs of the Economic Opportunity Act; and Small Business Administration programs.

Finally, there is a third and much larger set of programs which, while not expressly designed for rural needs, have had some impact upon the rural population. The list is far too long to detail here but includes such authorizations as Medicare and Medicaid, the Elementary and Secondary Education Program, the Interstate Highway System, Civil Rights, and Social Security.

The evaluation of public policy—even one small piece of one act—is no small task. If our experience with planning, programming and budgeting systems (PPBS) in the Federal Government has given us anything, it has been an even healthier respect for the complexities and hazards of meaningful program evaluation. But at the risk of oversimplifying I believe one can identify some overall forces at work within these programs that reflect on their performance.

First, the programs designed exclusively for rural needs have generally been preoccupied with the aims of improved production efficiency and economic adjustment of the firm and the industry. Program benefits have been linked principally to land and capital resources.

Second, these particular programs performed rather well. There is substantial agreement among students of the subject that the farm programs developed in the 1930's and continued in varying forms to the present day stabilized an inherently unstable agricultural economy and thereby contributed in some measure to the orderly growth of the overall national economy. Such policies had the additional side effect of stimulating the rate of adoption of new technology, thereby releasing resources, principally labor, for employment in other socially useful endeavors. Unfortunately, not all of these resources were in the appropriate form or place for nonfarm employment, and

* All views expressed in this paper are my own and should not be interpreted as the official policy of any federal agency. I would like to acknowledge the helpful comments of Michael Brewer, William Motes, and Derek Schoen.

LYNN M. DAFT *is with the Office of Economic Opportunity, on detail from the U. S. Department of Agriculture.*

therefore many remained in an underemployed state.

Third, rural programs have not usually addressed needs of the individual or the community. Rural people with little or no holdings of land or capital were in substantial measure abandoned by public policy. We have evidenced through our policies a much greater willingness to intervene in commodity markets than in rural labor markets.

Finally, those programs designed to meet human resource and community needs have generally been delivered more effectively within urban than in rural settings. A recent locational analysis found that federal expenditures in fiscal year 1969 (adjusted for population) significantly favor central cities, the richest counties, the fastest growing counties, and the very large metropolitan areas (population in excess of 1 million) [9, p. 51]. Those categories for which rural areas received a proportionally larger share of program funds included agriculture, recreation, regional development, ground transportation, business and farm loan, and development loan programs. Those categories for which rural areas fared poorly (and exceedingly so in the first three) included vocational education and manpower training, housing loans, defense contracts, defense payrolls, and health services and care.

Policy-Making Determinants

What are some of the more important causal elements that underly this performance? Future improvements will depend on our ability to identify these determinants and to recast them. For the sake of convenience, I shall separate them into two sets: those that are in some way unique to the rural setting and those that transcend any particular sector and apply to the policy-making climate of the Federal Government in general.

Rural setting

"Rural" policies.— Some years ago Karl Fox observed,

> The major problem of rural society in the United States is our institutionalized belief that a rural society exists and can be manipulated successfully apart from society as a whole [4].

Unfortunately, many present-day policy makers still cling to this belief. Legislators and administrators continue to attempt to force programs into rural molds which they do not fit. To further complicate matters, the target populations of these programs rarely coincide. What one agency labels rural, another labels urban.

Although this may at first be dismissed as little more than a problem of semantics, I believe a more basic difference is involved. The "rural policy" approach is too frequently rooted in the past, in nostalgia, in what the world used to look like, and not in how it appears today or is likely to appear tomorrow.

Continuing to make this distinction in policy making leads to obvious dangers: (1) It attempts, by legislative or administrative edict, to establish arbitrary program boundaries; (2) it is grounded in a stereotype image of rural that fails to capture the diversity that exists in reality; and (3) it results in policies that are often more concerned with circumventing or delaying change than in accommodating it through realistic forms of adjustment.

Institutional advocacy.— In the late 1800's and early 1900's agriculture was the mainstay of the rural economy, indeed of the national economy itself for a time. It was not until the late 1800's that our nation's nonfarm population exceeded its farm population. During this era agricultural policy was rural policy, and vice versa. So it was that the Secretary of Agriculture, the farmers' representative at the Cabinet table, also became rural America's representative.

For a time this was a comfortable match. The programs for which the Department of Agriculture held operating responsibility generally addressed those issues of greatest significance and concern to rural Americans. Yet as agriculture's relative importance to the rural economy diminished, the correspondence of farm issues to rural issues faded. Price supports, supervised farm credit, and the multitude of other agriculturally related programs aided an increasingly smaller share of the rural population. Other issues—nonfarm job opportunities, health care, education, transportation—assumed greater relevancy.

Despite these changes in the rural sector's nature and needs, the Department of Agriculture has continued to serve as rural America's advocate in the Federal Government's councils. In some administrations this responsibility has been made explicit; in others it remained implicit, based more on custom than formal agreement.

The most frequently cited justifications for

the Department's continuing to play this role have been (a) its extensive network of personnel, offices, and working relationships throughout the nation and (b) its familiarity and identification with the needs and capabilities of rural people and institutions.

But these are no longer enough. The Department of Agriculture simply does not have sufficient control over the design and implementation of enough key programs to effect a unilaterally defined rural policy. Neither does any other single federal agency. This is an institutional reality that must be faced if policy and programs are to be brought into concert.

"Place" versus "people".— As noted above, many of the public policies impacting on rural areas have been attached to capital and land rather than labor. In part this can be traced to the nature of the agricultural supply problem. Policy makers were drawn to control of the land input in an effort to curtail farm production because it was more easily controlled than most other factors. In the nonfarm economy the reasons were more roundabout, yet the purpose was essentially the same: to protect fixed investments endangered by major economic disequilibrium. But regardless of the cause, the effect was to abandon much of the human adjustment problem to the dictates of the market economy.

Depressed area focus.— At the time regional development issues were placed on the national agenda in the 1960's conditions in the more economically lagging areas of the country were severely depressed. Not surprisingly, most of the efforts begun during this period— the Economic Development Administration, the regional commissions, and parts of the Economic Opportunity Act—sought to strike directly at those pockets of severest depression. In large measure the approach was curative rather than preventive. The Economic Development Administration pursued a "worst first" strategy for regional development.

There is mounting evidence of the general ineffectiveness of this approach. The economic and social forces underlying the areas' depressed conditions often proved to be of far greater strength and pervasiveness than anticipated.

The Appalachian Regional Commission has perhaps been more resourceful than its sister agencies in avoiding sinking large investments into areas of low growth potential. Still, the Appalachian region is itself defined by criteria representing economic depression. The Economic Development Administration has more recently sought to alter its strategy by channelling a portion of its assistance into "growth centers" servicing nearby redevelopment areas. Yet the constraints of the existing authorization still result in most of the funding going to those highly depressed areas that exhibit the least likelihood of achievement.

Overall policy-making setting

Policies . . . what policies?—Thus far I have used the term policy rather loosely, often equating it with program. Most of the specific cases I have used in illustration have been programs, not policies. The reason is simple. Over the past decade policy formulation has been all but buried in a proliferation of narrow, categorical programs. From 1960 through 1968 the number of domestic grant-in-aid programs increased more than eight-fold [7, p. 5]. The current catalogue of federal assistance programs has over 1,000 separate program entries.

Any single issue of national significance, such as poverty or housing or regional development, embraces a long list of program remedies. Each program has its own purpose, its own eligibility criteria, its own administrative machinery. Many report to separate congressional committees for authorizations and appropriations. Is it any wonder, therefore, that a sense of common direction or purpose has failed to evolve for most of these issues, including those concerned with rural affairs?

Beyond its immediate effect on program administration, the absence of clear-cut policy has also considerably confused the communication between government and constituent. In the course of looking for clues that reflect an unstated policy, policy significance is attached to administrative actions that are not indicative of policy at all. In time program administrators become sensitive to this and consequently take to worrying more and more about program appearance and less and less about program substance.

Functional feudalism.— Federal programs have a way of developing their own bureaucratic autonomy and of making control difficult under the best of circumstances. Narrow constituencies extending vertically from grass roots beneficiaries through interest group lobbies, agency bureaucracies, and congressional

committees develop around individual programs. The constituencies enable and promote the autonomy of the programs to which they attach. With the increasing specialization of programs and the phenomenal growth in their number, control has been even further eroded. Critical program decisions are increasingly made by those in the "technostructure" of individual agencies.

> Operational matters flow to the top—as central staffs become engrossed in subduing outlying bureaucracies—and policy-making emerges at the bottom. At the top minor problems squeeze out major ones, and individuals lower down the echelons who have the time for reflection and mischief-making take up issues of fundamental philosophical and political significance [10, p. 42].

This problem is not, of course, limited to the federal level. In some respects the problem of executive control within states is even more acute. The proliferation of federal programs has itself necessitated the creation of additional machinery within the states. The Department of Health, Education, and Welfare alone requires nearly 40 state plans annually for a variety of categorical assistance.

But beyond the customary problems of controlling and directing a large administrative organization, most governors must also contend with sharing their responsibilities with independently elected executives and with complex systems of boards and commissions, most with appointive terms that put them beyond effective gubernatorial control. As of 1967 only 4 of the 50 states elected no other executive official independently (excluding auditors). In short:

> Structural fragmentation amounting to chaos, departmental independence bordering on anarchy, and absence of suitable tools for planning, personnel management, or financial control render an effective administrative performance almost impossible for most governors [2, p. 49].

Conditions within local government are no better, particularly in rural areas, but for different reasons—a large number of very small units, about 60,000 outside metropolitan areas; a myriad of overlapping layers; and, a general lack of professionalism. Only about half of all elected officials are paid for their services and five-sixths serve only part-time [1, p. 17].

Such evidence has led Peter Drucker to conclude:

> Modern government has become ungovernable. There is no government today that can still claim control of its bureaucracy and of its various agencies. Government agencies are all becoming autonomous, ends in themselves, and directed by their own desire for power, their own narrow vision rather than by national policy [3, p. 8].

Centralization of program authority.—Beyond creating an ever-growing number of specialized programs with relatively narrow, functional aims, authority for the implementation of these programs has increasingly been lodged at the national level. This has occurred for several reasons. In part it was a function of the issues coming to prominence—civil rights, poverty, regional development, pollution, etc. —issues of national import. Neither cause nor effect is constrained by state and local boundaries. Furthermore, the magnitude of the tasks could not begin to be matched by local resources. The full, coordinated force of the Federal establishment was needed. And, finally, there was the lurking suspicion that units of government at a lower level were either incapable or unwilling to confront these issues head-on. Indeed, one need not look very far to find evidence that some of these governments had openly contributed to the problems.

While this continuation of the shift toward centralization that began in the 1930's served the useful purpose of focusing national attention and gaining a commitment of national resources "to do something" about these problems, it had other less desirable effects. It made more evident the limitations of centralized decision making. And there are several: First, centralization has necessarily separated the point of problem identification from the point of program design. Program solutions are designed for the problem as seen from afar. Yet the problems often take on different dimensions when viewed close up. Information regarding the problem is seldom generated by the program developer, often contributing to an incongruity between program and problem. There is a tendency, furthermore, to attempt to treat divergent versions of the same problem with a universal solution. Second, given the communication problems imposed by the multiplicity of grantees and grantors geographically separated and the fact that taxpayer money is involved, close management is demanded. This requires an extensive system of application forms, agency reviews, status reports, and all

the various and sundry other items that make up the conventional "bureaucratic red tape." Finally, with the removal of decision making further from the electorate and the general invisibility of those who make the decisions, there has ensued a serious loss of accountability. Those who are most directly accountable to the electorate make comparatively few decisions; those who make most of the decisions are separated, if not entirely divorced, from political accountability.

Implications for the Future

It is a hallmark of our rapidly changing times that we almost always seem to stand at the brink of a critical turning point. Today is no exception. Several things are happening or are about to happen that would seem to have portent for future public policies.

Several key legislative measures will expire within the next few months. These include authorizations for the Economic Development Administration, the Appalachian Regional Commission, the Title V Regional Commissions, and the Office of Economic Opportunity. None of these programs can claim to have been an unqualified success, their genuine accomplishments notwithstanding. It would be surprising, therefore, if at least some of these authorizations were not substantially altered.

In addition to changes in existing programs and policies, several important new ones are waiting in the wings. Two of these—welfare reform and revenue sharing—have the approval and support of the present Administration. Other pending or recently authorized proposals having special significance for rural areas include those relating to new towns, industrial tax incentives, rural credit banks, and rural development highways.

In some respects, therefore, we stand at a policy-making watershed. Decisions made within the next few months will determine the principal configuration of this nation's economic development policy over the next few years. In light of the foregoing assessment, what suggestions can be made for future policy? What are the elements of a leading edge?

Public policy should provide for evolving processes by which debate and trade-offs can occur and whereby constituent interests can reach consensus. Beyond offering the usual static collection of categorical programs, it should set the stage for a dynamic and continuing process of public problem resolution. Furthermore, the process must be of sufficient breadth to cut across the spectrum of major community interests. To establish separate deliberative processes around each of many functional interests, as several existing "grass roots" programs now do, will not lead to the overall community consensus that is so badly needed.

Several innovative efforts to establish such processes are under way. At the federal level two deserve special mention—the federal-wide Planning, Programming, Budgeting System (PPBS) and the Domestic Affairs Council (DAC). The former process is used to resolve detailed policy questions; the latter is reserved for more global issues. While opinions differ as to the degree of success of PPBS, there is general agreement that the system has materially improved the rationality and orderliness of budget making. It can become an even more effective tool, however, if more attention is devoted to the generation and application of well-developed analysis; policy issues of longer-run consequence; overcoming the foot-dragging of hostile bureaus; and developing increased support for and understanding of the system on the part of key policy makers.

The Domestic Affairs Council is too new to the policy-making scene to provide a basis for evaluation. Its first major test will come in the preparation of the Administration's domestic program for 1971 and in designing replacements for key legislation about to expire. The most apparent needs of the Council are for greater access to impartial, highly responsive analytical and informational resources and greater isolation from pedestrian details of comparatively minor policy significance.

Similar innovations are being tried at state and local levels. Several governors have organized PPBS-type units within their offices. Several states are also in the midst of establishing Departments of Community Affairs to assume responsibility for the overall coordination of state development activities.

At the local levels, the brightest hope for evolving a policy process in the nonmetropolitan setting would seem to lie with the multicounty planning and development district concept. Many states are responding to guidelines established by the Office of Management and Budget (Circular No. A-95) and are identifying common systems of substate districts and are designating clearinghouse agencies at both state and district levels to review and comment on applications for a list of some 50 fed-

eral programs. As of July 1970, 50 state clearinghouses and 334 substate clearing houses covering nearly 1,400 counties had been established, 132 of them in nonmetropolitan areas of 22 states. Eventually, this can lead to a nationwide system of about 500 clearinghouses through which state and federal assistance can be channelled.

These district organizations are obviously not without their problems too. If they are to realize their full potential, it will be necessary, among other things, to bring greater order to the grab-bag mixture of federal funding sources that now provide the bulk of their support; to inject greater meaning and relevancy into the planning process by securing it more directly to noncategorical financial assistance; to end the internecine competition of state and federal agencies over who will be credited with leadership; and to bring about a closer integration of the districts with local government, including the assumption of appropriate government functions.

Public policy should enhance the adjustment capabilities of those people whose lives will be disturbed by major economic and social change. As noted above, a preponderence of the policies directed specifically toward rural areas have done little if anything to provide for the adjustment of the individual. A major drawback to forming programs and policies around narrow, functional constituencies is that the larger social interest is often overlooked. Thus, while the benefits befalling the constituency in question are well-represented, the secondary effects—many of which entail costs to other individuals—are not.

Public policy should seek to harness the central economic and social forces of the private sector for the attainment of policy goals. Too many programs either attempt to meet these forces head-on or ignore them altogether. Much of our economic development assistance has sought to prop up or rejuvenate economically depressed areas. This assistance has often taken the form of public works aid—highways in the case of Appalachia, water and sewer systems in the case of EDA. Large portions of the United States are eligible for this aid; nearly 1,000 areas are eligible for EDA assistance alone. Thus, in an effort to provide something for everyone, present policies have had the effect of spreading resources thinly and locating them in places and forms that have proven to be of marginal effectiveness.

Given the level of available federal resources and the strengths of the economic and social adjustments underway, it is unlikely such efforts will ever achieve notable success. Although it will entail some hard political decisions, we must recognize that not every crossroads settlement that chooses to incorporate and call itself a community should be the recipient of public works aid. A far more persuasive case can be made for harnessing the forces of growth associated with small- and medium-scale urbanization and using that momentum for the attainment of regional development aims. The programs of EDA and ARC have moved in this direction, but not far enough.

The same principle merits application in policies guiding the use of natural resources. As the preceeding papers in this session have shown, the demands on these resources are changing rapidly. Nonagricultural uses are growing in prominence. Our concern with the qualitative dimensions of the physical environment, coupled with changing consumption patterns, strongly suggest a substantial increase in the social utility of resources that are kept out of commodity production. Quite apart from the problems of overproduction, it would seem that the positive value of natural environmental amenities and landscape protection will rise relative to the value of increased food and fiber production. Future policy should mirror this shift.

Public policy should seek to internalize a system of accountability. Too many of our existing programs are, in a sense, out of public control. Instead, they are under the benevolent direction of narrow constituencies. Accountability can be improved in a number of ways. The fledgling institutional devices mentioned earlier can help by providing the executive with greater control over functional program elements. The transfer of many of the more detailed management responsibilities to lower levels of government where accountability is more visible and more direct would also help. Revenue sharing could help set the stage for this transfer, although insufficient attention at an early stage to strengthening the capacity of state and local governments to deal with functional interests could result in failure. Greater use of the private sector, as suggested by Peter Drucker, is yet another avenue that merits further exploration [3].

Public policy making has been aptly termed

"the science of muddling through" [6]. Some students of the subject find value in a system that minimizes debate over policy objectives, that moves toward the resolution of issues in incremental steps, and that fosters an intricate system of interest advocacy. Perhaps there is. But there are also obvious drawbacks, some of which I have sought to describe. Perhaps, with the adoption of changes such as those described above, we can evolve a process that muddles less and governs more.

Soviet Agriculture Revisited

CHAIRMAN: HARRY C. TRELOGAN, STATISTICAL REPORTING SERVICE, USDA

Soviet Agriculture Revisited

D. GALE JOHNSON

IN JULY and August 1955 I had the opportunity of visiting the Soviet Union as a member of an agricultural delegation. At that time I visited 30 farms as well as several agricultural research and educational institutions, factories, machine testing stations, and machine tractor stations. My notes of a meeting on the last day of our visit indicates that at least some things have changed very little in 15 years. The meeting was at the Ministry of Agriculture and the Ministry of State Farms; the presumed purpose of the meeting was for the members of the delegation to make recommendations concerning agricultural policy in the Soviet Union. My notes include the following: "At this meeting Soth[1] presented our views that we were not provided the opportunity that had been promised to see what we wanted to see. Instead, we had been taken on a conducted tour with a fixed schedule that could not be changed. He also pointed out that the delegation was handicapped in making recommendations because we were not given basic economic data on Soviet agriculture. We considered this information absolutely basic to the study of any country. Though data on prices, income, production, livestock numbers, and acreages were promised us, the promise was never fulfilled."

While the amount of data on Soviet agriculture has increased substantially since 1955 (the first economic statistical handbook since 1939 was published in 1956), much important information is still not available and could not be obtained by those who attended the XIVth International Conference of Agricultural Economists in Minsk in 1970. I can personally attest to the failure to provide information that was promised, even when the promise was made by a high public official at a public meeting. In response to a question that I asked about the the regional price variations for meat and milk, the Minister of Agriculture, V. V. Matskevich, stated that if I saw him after the session all the information that I desired would be given to me. I did see him after the session, made further inquiries of some of his associates at Minsk, and also made inquiries in Moscow. The latest response was that the price schedules, even though they went into effect May 1, 1970 (and in major part had been in effect for five years), had not yet been published. I still have not received the information.

I make these personal comments to make it clear that my remarks about Soviet agriculture will reflect little that was learned on my recent visit to the Soviet Union. If the hosts had desired to minimize what the foreigners who came to their country could learn about agriculture, they achieved their objective. On the average, including the post-conference tours, participants visited about three carefully selected farms and one or two research institutions. The papers at the conference were singularly uninformative; one can only assume that this was by design since it would have been impossible for intelligent and informed individuals to say so little without making a conscious effort to do so.

I am baffled by the performance of our Soviet colleagues. There seems to be no excuse for such monumental reticence about displaying Soviet agriculture to the outsider. It is true that Soviet agriculture does not compare favorably on many critieria to the agriculture of Canada, Australia, or the United States, or much of Western Europe, but compared to the rest of the world there is much that can be shown with pride. There are many aspects of Soviet agricultural policy that are subject to serious criticism, but few nations now have an agricultural policy of which they can be proud. There is no objective reason why Soviet agricultural economists should not be more open about their agriculture; their failure to be more open leaves one puzzled. It is my opinion that the general circumstances of Soviet agriculture are more favorable than the impression gained by most conference participants; many par-

[1] Lauren Soth, editor of the editorial pages of the *Des Moines Register* and the person who was primarily responsible for the exchange of delegations between the United States and the USSR in 1955.

D. GALE JOHNSON is *professor of economics at the University of Chicago.*

ticipants seemed to conclude that so little information was transmitted necessarily because the agricultural situation is quite adverse.

It is a sad commentary that the most informative presentation on Soviet agriculture made at the conference was by Minister Matskevich. He is an able agricultural economist, so one should not have been surprised to hear a useful and informative presentation; but one can be disappointed that the special volume prepared for the conference, *Agriculture of the Soviet Union* [4] and the several speeches were much less informative than the speeches given by L. I. Brezhnev in recent months and years.

In these remarks I shall try to give a review of some developments in Soviet agriculture for the decade from 1958 through 1968. Both 1958 and 1968 were very good years climatically, and more data are available for 1968 than for 1969. Between 1958 and 1968 total agricultural output increased by 35 percent, according to the USDA index of farm output [16]. Total population increased by 15 percent; per capita agricultural output increased by 17 percent [16]. The increase in output per capita was almost identical with that achieved in all industrial countries and greater than in the United States (4 percent).

The increase in output has done little to correct or offset high food prices. A market basket of food priced in April–May 1967 in New York, Moscow, London, Munich, and Paris indicated that if official exchange rates are accepted the basket cost $34.60 in Moscow, $16.66 in London, and $18.27 in New York [11, p. 276]. The highest cost, except for Moscow, was in Munich where it was $22.48. The amount of working time required to purchase the basket was 7.3 hours in New York and 59.2 in Moscow; in Paris 32.1 hours were required [11, p. 276].

Input Changes

The increase in farm output was associated with a number of input changes. Average annual employment in agriculture probably declined from about 43.7 million in 1958 [3, p. 5] to about 39.10 million in 1968 [9, p. 75]; in this series almost all of the decline occurred between 1958 and 1960. The change in employment after 1960 has been remarkably slow by comparison with developments in Western Europe, but not at all different from conditions in the United States when about 40 percent of the labor force was engaged in agriculture (about 1890).

The total area of cultivated land, approximately 220–224 million hectares, changed little if at all over the decade [15, p. 20; 13, p. 55]. The area of fallow land is included in the total for arable land; and it varied significantly over the period, declining from 24 million hectares in 1958 to 6 million in 1963, then increasing to 17 million hectares in 1966.

There were striking increases in some inputs produced by the nonfarm sector. The number of tractors almost doubled, from 924,000 at the beginning of 1958 [10, p. 393] to 1,821,000 by the end of 1968 [13, p. 55]. Fertilizer deliveries (in terms of plant nutrients) increased from 2.46 million tons in 1958 [15, p. 34] to 8.25 million tons in 1968 [13, p. 55], or 235 percent. The increase in the United States over the same period was 141 percent; and fertilizer use in the USSR in 1968 was 70 percent of the U.S. use in the same year. The number of combines increased by less than a fifth, despite the continuing difficulty of completing grain harvesting in a reasonable period of time [15, p. 33; 9, p. 28].

Investment

The decade under review has witnessed an enormous increase in investment in agriculture —from 5.5 billion rubles in 1958 [15, p. 27] to 14.1 billion rubles in 1968 [12, p. 7]. If anything, the purchasing power of the investment ruble in 1968 was greater than in 1958. While the figures are probably not fully comparable, it is worth noting that in 1968 gross capital expenditures on U.S. farms were $6.1 billion. Since 1968, annual investment in Soviet agriculture has increased more than 20 percent. While value added in Soviet agriculture is probably greater than in the United States, the ratio of investment to value added is almost certainly substantially higher in the USSR than in the United States.

For the Ninth Five-Year Plan the total of state and collective farm investment is planned at 124 billion rubles, or an annual rate of 25 billion. While this figure may include some investments of a social and cultural nature, and perhaps governmental, its magnitude should not be underestimated.

The Private Plots—A Touchy Point

Asking a question about private plots does little to increase one's popularity among agriculturalists in the Soviet Union. Minister Matskevich ridiculed the factual basis of a question

raised at the Minsk meeting about the importance and relative productivity of inputs on the private plots. At a meeting with the director of an agricultural economics research institute in Kiev I asked whether the institute did any research on production problems on the private plots. The director did not wait until the translation of the question was completed before he entered upon what can only be described as a tirade against Western economists who exaggerate the importance of the private plots in agricultural output. It was not until the question was put twice more that he listened to the end and his anger subsided. His response was that his institute did little work on the economics of private plots, but other economists in the USSR had published on the topic.

The private plots are very important in the Soviet Union, despite any disclaimers that might be made to the effect that plots are really not separate from socialized agriculture. According to USDA calculations, 30 percent of the gross agricultural output is produced on the more than 30 million private plots [13, p. 56]. According to official Soviet data, almost 40 percent of meat and milk and 60 percent of eggs, as well as over half of all fruits and vegetables, are grown on private plots [13, p. 57]. The private plots have 3 percent of the cultivated area [13, p. 57]; and, perhaps somewhat surprisingly, the gross output per worker is approximately the same on the private plots as in the socialized sector.

The existence of the private plots has a significant negative effect upon the socialized sector, especially upon the collective farms. Even though payments per man-day of work on collective farms more than doubled between 1958 and 1968, my colleague, Arcadius Kahan, estimates that it is still true that an individual can earn more from a day's work on his private plot than he can by working on the collective farm.

One of the important reasons for the increased payments to collective farms was to increase labor participation in the socialized sector by the members of the collective farms. The evidence indicates that nothing has happened—neither the number of days worked per worker nor the seasonal distribution of work changed during the 1960's. One of the problems of labor use on collective farms has been the conflict during critical periods between work on the farms and on the private plots. It is still necessary for several million people, often college students, to leave the cities to work on farms during the harvest season; and I have recently seen a reference to the same phenomenon during the spring planting season.

Changes in Labor Requirements

As noted above, there were major increases in current inputs purchased from the nonfarm sector and a very high level of investment achieved in the 1958–68 period. Farm output did increase significantly during the period, and to some very significant extent the output increase can be attributed to the increased inputs. However, an important reason for the increased inputs and investment is to increase output per worker. Data presented in *Agriculture of the Soviet Union* [4] on average labor requirements in the USSR permit a comparison of changes in labor requirement for the period 1960–68 with a similar period for the United States.[2] These data are given in Table 1, as are the estimates for the United States. The primary emphasis is not upon the absolute levels of labor requirements in the two economies but upon changes over the eight-year period.

The largest reduction in labor requirements in the USSR was for grain produced on collective farms—62 percent; a major change also occurred in pig production on both collective and state farms. There does appear to be a pattern to the instances in which reductions in labor requirements in the USSR were either greater or less than in the United States. When the labor requirements per unit of output for the beginning year were approximately ten or more times those in the United States, the reduction in labor requirements in the USSR tended to be greater than in the United States. When the original difference in labor requirements was less than seven or eight, the reduction in labor requirements in the USSR tended to be less than in the United States.

The increasing and high level of investment did not seem to pay off in terms of significantly reducing the large gap between labor requirements in the two agricultures. The reduction in labor requirements per unit of output in the USSR was probably about 30 percent. This is a significant reduction in a period of eight years; however, the investment costs of achieving such a reduction appear to be very high in comparison

[2] The time periods are not identical since for the United States the comparisons are for five-year periods that have midpoints eight years apart (1957 to 1965).

Table 1. Labor requirements, USSR and United States (man-hours per center)[a]

Product	USSR Collective farms 1960	1968	Index[b]	USSR State farms 1960	1968	Index[b]	United States 1955–1959	1963–1967	Index[b]

to the costs of an equal reduction in the United States.

Agricultural Price Policy

While this paper is primarily concerned with a discussion of Soviet agriculture from 1958 through 1968, it is not possible to adequately understand the changes in price policy without going back to the late Stalin era. In 1952 (and the years before) the procurement prices for almost all food products were so low as to be confiscatory. The price of grain for compulsory deliveries in 1952 was 9.7 rubles per ton, and no grain was delivered at the above-quota price of 12.5 rubles in that year [7, p. 79].[3] Thus the average price for a bushel of wheat was the equivalent of 30 cents. In 1952 the average procurement prices for cattle and hogs were, respectively, 50 rubles and 70 rubles per ton [7, p. 79]. These would convert, at the official rate of exchange, into prices of approximately $2.50 and $3.50 per hundredweight.

The price of cotton, however, was very favorable at 315 rubles per ton of raw cotton;[4] including the associated value of cottonseed, this works out to about 45 cents per pound of lint.

Significant increases in procurement prices for grain, potatoes, vegetables, and livestock products were announced in 1953; further increases occurred in 1955 (grain) and in 1956. In 1958 the multiple price system was abolished in favor of a single price for all procurements. Data in Table 2 indicate 1958 grain prices were 7 times as high as in 1952; 8 times for potatoes; 5.5 times for meat; 4 times for milk; 3 times for eggs. The 1958 cotton price was approximately the same as in 1952, while the prices for wool, sugar beets, and flax were a little more than double.

Some farm prices were increased in 1962 and there were major increases in livestock and butter prices. In 1965 livestock prices were once again increased substantially (29 percent); the increase in the price of milk was approximately 16 percent (see Table 2).

In 1965 the policy of a single purchase price was abandoned in favor of a multiple price system for grains; the premium for deliveries in excess of the purchase plan was set at 50 percent. A similar change in policy was introduced for livestock and milk in 1970, subject to a condition to be noted later.

The other 1965 innovation in price policy was the introduction of large zonal differences in prices. The basis for the zonal prices is stated by M. M. Sokolov: "The average cost of production in every specialized zone determines the purchase price for farm produce. In calculating the average cost of production, the last three to five years are taken. Staple crops and the key branches of agriculture can have the greatest divergences from value within a given zone, e.g., grain in the Kuban and the virgin lands, cotton in Central Asia, and flax in the areas of Non-Chernozem Zone. There the purchase price stimulates production of those farm products which have the lowest cost in the given area." [4, p. 194].

The differences in the zonal prices are very great (see Table 3). For example, the procurement price for wheat in the Ukraine (excluding

[3] All references to rubles are to the current ruble which has an official exchange rate, according to the government of the Soviet Union, of $1.11. This is the rate at which conversions are made into dollars. Unless indicated to the contrary, all weights and measures are metric.

the Poleyse region) and Moldavia is 76 rubles per ton; in Belorussia, the Poleyse region of the Ukraine, the Baltic republics, and the large parts of the RSFSR, the price is 130 rubles. For cattle the procurement price is about 1100 rubles per ton in the Ukraine and 1600 rubles in Belorussia, which borders on the Ukraine. As indicated by the quotation from Sokolov, the variations in average costs of production among zones are at least as large as the zonal price differences.

The second part of the Sokolov quotation contains a rather explicit criticism of the zonal price differentiation policy. As the writer notes, within a given zone the purchase price "stimulates the production of those farm products which have the lowest cost in the given area." If this is true within a zone, why would it not be true among zones if prices were differentiated by only the costs of marketing and transportation?

There are probably two main reasons why such large zonal price differences are required. The first is the absence of any charge for land; the collective farms in the Kuban have been given an enormous source of productive power in their rich land while the collective farms in Central Nonblack Soil area received very little. If the Soviet government charged rent reasonably related to the value and productivity of land, at least part of the regional income differences that would exist with uniform prices (except for transportation costs to the deficit consumer areas) would be eliminated. But not all.

The second factor in the substantial regional income differences that have existed in the past (and still persist though to a lesser degree) has been the absence of labor mobility among collective farms. There are very substantial differences in the labor/land ratio, with the highest labor/land ratios existing in the central and northwestern regions. These comparisons do not include the Central Asia areas with their labor-intensive crops. Failure of labor mobility to eliminate regional income differentials within agriculture is not unique to the USSR, of course. But the combined lack of land rent and limited labor mobility created exceedingly serious discrepancies in farm incomes, and the response was widely differentiated purchase prices by zones. In terms of efficiency in production, the solution is a costly one, but failing the imposition of land rent and improving intra-agricultural labor mobility it was probably the most reasonable solution.

The purchase prices for livestock products that were announced in July 1970 have a num-

Table 3. Minimum and maximum zonal purchase prices, 1965, and average procurement prices, 1967, USSR (rubles per ton)

	Number of zones	1965 zonal prices: Minimum	1965 zonal prices: Maximum	1967 average procurement price
Wheat	15	67	130	103[a]
Barley	7	48	90	
Sugarbeets	5	27	40	27
Sunflower	6	165	225	214
Milk	15	130	230	156

[a] All grain; in 1967 RSFSR average price of wheat was 99 rubles per ton [1, p. 148].

ber of interesting features [2, p. 2]. First, there are no seasonal price differentials. Second, very substantial penalities are imposed for cattle, sheep, and hogs that are of less than average fatness—reductions of 20 to 25 percent. Third, indicating the strong emphasis still given to increasing the supply of fat, premiums of 20 percent are paid for cattle and sheep of better than average fatness. Fourth, a premium of 50 percent is to be paid for all livestock products sold in excess of the annual plans by collective and state farms.

It is of more than passing interest that the receipt of the premium for sales in excess of the annual plan requires "that there has been an increase in the number of animals the farm had on hand at the beginning of the year" [2, p. 3]. In the Eighth Five-Year Plan there was no reference to goals for livestock numbers. This was presumably an acceptance of the tenet that the individual farms should have more freedom in their decision making so long as the annual purchase plans were met. But apparently old ideas die hard. Now pressure is to be put upon farms to continuously increase livestock numbers, since this is a requirement for receiving the premium.

The purchase price for cattle in Belorussia is 1600 rubles per ton (72.7 rubles per hundredweight). In addition to this base price, there is a marginal pricing scheme for young cattle that is probably without peer in the world. If a calf weighs between 350 and 400 kilograms, the supplement to the base price is 35 percent; if the weight is over 400 kilograms, the premium is 50 percent. The marginal gain from increasing weight from 325 to 375 kilograms would be 290 rubles (263.6 rubles per hundredweight) and from 375 to 425 kilograms, 210 rubles (190.9 rubles per hundredweight). It was no wonder that one of our Irish colleagues at the meeting said that he was going back home to argue that the Irish farmers should join the USSR rather than the EEC!

While one of the reasons for the zonal price differences was to reduce regional income differentials, the premium for above-plan deliveries has two important effects upon income. First, given that planned sales are now fixed for a five-year period and are presumably not adjusted to year-to-year changes in output, the incomes of collective farms will fluctuate more from year to year than would be the case if a single price were paid. In a year when yields are low, no sales will be made at the premium price; in a year (such as 1968) when yields of the grains are high, a substantial fraction of sales to the procurement agencies will be at the premium price.

Second, either errors in establishing the purchase plans for given farms or differences in conditions favoring output increases within a plan period can result in significant income differentials among farms. A farm with a favorable delivery plan will be able to sell more at the premium price, while a farm that has a greater than average rate of output growth will gain significantly compared to a farm with a stable output. Differences in income would occur under a single price, but differences are exaggerated by the multiple price system.

The high absolute prices paid to farms for livestock and milk are apparently higher than Soviet planners believe Soviet consumers would accept. Consumer prices for meat and milk in the state stores have remained unchanged since 1962 when, or so it was rumored, there was considerable public resentment of higher meat and milk prices. Consequently all of the costs of price increases for livestock and milk since 1962 have been paid from the budget. I do not know how large the subsidy is, though rough calculations that Alec Nove and I made in Minsk indicated that the total for 1970 might be as much as 10 billion rubles. Efforts at Minsk to determine the amount of the meat and milk subsidy were unavailing, though it is perhaps worthy of note that no one contradicted the 10 billion ruble estimate.

Earlier it was shown that the average prices received by collective farms for sales to governmental agencies had increased substantially between 1952 and 1968, especially so in livestock and grains. The last column in Table 3 gives the average procurement prices for 1967. Since then cotton and milk prices have been increased; the average purchase price for milk should now be at least 190 rubles, and this includes no premium for above-plan deliveries. Any comparison with producer prices in other countries is complicated of course by lack of information concerning the true exchange value of the ruble. At the official exchange rate, the average procurement prices are high in comparison with the EEC, the differences for cattle and hog prices being of the order of 100–125 percent

Boev [1, p. 175] has made some comparisons between the number of tons of wheat required to purchase certain items of farm machinery in the USSR, USA, Canada, and West

Germany. In 1966 a tractor that cost 20 tons of wheat in the USSR cost 75 tons in the United States, 68 tons in Canada, and 40 tons in West Germany. A combine that cost 40 tons of wheat in the USSR cost 95, 126, and 117 tons, respectively, in the United States, Canada, and West Germany. If these comparisons are typical of output price/input price relationships in the USSR, the official rate of exchange may not be invalid for making international comparisons of output prices. However, one can discount the official rate of exchange by half and still find that most of the USSR prices are at least as high as those received by farmers in the United States. In any case, I think it would be most inappropriate to use the black market exchange rates, which range from 3 to as many as 6 rubles per dollar, for purposes of comparison.

Returns to Labor

Efforts have been made in recent years to assure that the higher prices are reflected in the incentives available to the collective farm members. A most important change has been the institution of guaranteed monthly wages. Formerly the majority of the farms paid only or largely at the end of the year, and since the funds available for distribution tended to be a residual after all other expenses and commitments were met, the payment varied widely from year to year. Another change has been the strong pressure from the government to raise the guaranteed payment to the level of comparable workers in the state farms. From the information given to us, the guaranteed pay for collective farm workers appears to be 3.6 rubles per day in the Ukraine and Belorussia. V. A. Tikhonov [11, p. 167] states that the annual income of collective farmers from the collective farm increased by 120 percent between 1960 and 1967. Assuming that there had been some small increase in pay to collective farm members between 1967 and 1969 and that the number of days worked per year has remained unchanged, this implies that average pay per day in 1960 was about 1.5 rubles per day.

Some Concluding Comments

The USSR has a high-cost agriculture. It is high cost in several senses. Consumer costs for a relatively limited selection of foods are high relative to incomes; even so, a large subsidy is required for meat and milk to make up the difference between prices paid to farms and prices paid by consumers. The level of investment in agriculture is high and is planned to increase even further during the next plan period. There is little reason to believe that much success will be made during the present decade in making Soviet agriculture both more efficient and more responsive to consumer demand.

There are many reasons for the high-cost status of Soviet agriculture. One is the policy of autarky in farm products combined with significant limitations in the quality of Soviet land resources. But other factors are clearly significant, including the very large size of farms in the socialized sector, the unwillingness of planning and control officials to permit a wider range of decision making at the farm level, the poor performance of research institutions in the fields of mechanization and animal breeding, and the generally inadequate functioning of farm machinery production and supply. Farm machinery is still of low quality, requiring high maintenance costs and frequent interruption of service for repair.

While I believe that family-operated farms are more efficient than collective and state farms, I am coming to the opinion that the shortcomings of the institutions of collective and state farms are not the primary causes of the present unsatisfactory state of Soviet agriculture. It is the framework of regulations and controls within which the farms must function, the inadequate functioning of the rest of the economy in supplying farms with appropriate inputs, and the failure of the marketing and distribution system to provide satisfactory and assured market outlets for perishable and semiperishable farm products that must bear much of the responsibility.

Despite frequent references to the role of incentives in economic activity, including agriculture, the real operating principle that seems to guide agricultural planners and officials is that the farms cannot be trusted to make the appropriate decisions. While there is a great deal of objective evidence to support this conclusion, the basic idea was well put in a speech at Minsk by A. M. Rumyantsev:

> Every collective farm cannot take into account society's real needs in agricultural products. This can be done only by socialist society as a whole. The latter makes the necessary information available to all collective farms in a centralized way, by drawing up its firm plan of purchasing farm products, by placing orders with these

farms and thus ensuring the stability of their production.

The firm plans may serve the interests of the bureaucrats, who apparently try to avoid uncertainty, or of the marketing and procurement agencies; but it is impossible to show how firm plans for a required minimum sale can be superior to the opportunity to sell any desired amount at firm prices. With the present level of prices paid to farms, the farms could produce more if the rest of the economy served them better. Much of Soviet agriculture has a relatively harsh natural environment and relatively little can be done about this. But its economic and political environment could be substantially improved. And only time will tell whether any significant changes are forthcoming. Recent decisions, including the Ninth Five-Year Plan and the 1970 price announcements, indicate that there is little prospect for significant change before 1976.

Discussion: DALE E. HATHAWAY, *Michigan State University*

Evaluating the professional progress in Soviet agricultural economics is difficult for one who does not read or speak the language; therefore my judgments are necessarily based upon the professional performance of the participants in the recent I.A.A.E. meeting and upon a longer visit in the Soviet Union three years ago, when I was accompanied by colleagues who were competent in the language.

I would make several observations on the recent meetings. The Russian-English translation was inadequate, and some of the Russian papers and comments may have suffered as a result. Second, most of the Russians attending the conference were older men, relatively high in the various bureaucracies; the younger men, in sharp contrast to the Western delegations, were absent. One Russian privately confirmed my impression of this latter point.

There was a noticeable lack of economic analysis in the content of the meetings and an excess of ideology in most of the Russian papers and comments. Moreover, unlike their U. S. counterparts who are anxious to discuss problems and policies, the Russians never admit they have any problems in agriculture and never really discussed policy issues at the meetings. However, in a country where open dissent often results in demotion or detention, the lack of counterparts to our Galbraiths and Cochranes is hardly surprising.

Unfortunately, this internal attitude is ex-

tended to international professional meetings. The extraordinary reaction of the Russians to the somewhat critical comments made by John Dillon of Australia and Dennis Bergmen of France was frightening as well as amusing. Westerners are accustomed to hearing critical policy evaluations made publicly and debated openly; it was clear the Russians were not.

The discussion groups varied in terms of depth and analytical content. In my own, a large group of Russians participated well after some initial confusion over ground rules and despite relatively poor sequential translation. The discussion on credit and capital reportedly went well. In many discussion groups, however, the Russians were reported to have presented prepared statements rather than to have participated in discussions.

My impression from this visit and the earlier one was that economic analysis has very little to do with the allocation of resources within or among farms. At the farm level it appears that the economist is primarily an accountant. Someone may have an excellent rationale for how resources are allocated, but it is never explained to visitors. Moreover, in discussing the training taken by some of the farm-level economists, I never found one who had had a course in production economics, which may explain why the agronomists and the party leaders make the local decisions on resource allocation.

I had been told of a new breed of Russian mathematical agricultural economist who is sophisticated in applications of linear programming and other modern techniques. These persons were not present in significant numbers at the meetings, nor was there any evidence on the farms that their work is being applied to improving resource use in Russian agriculture. Herein lies the rub in judging the quality of work done by Soviet agricultural economists. Their analysis and recommendations are not generally known to outsiders. Decisions in the Soviet economy clearly are political to a large extent, and it is impossible to tell what part, if any, economic analysis plays. Indeed, one wonders whether the individual economist knows where his own analysis blends into party dogma. We can only imagine the exciting discussions one might have with Soviet colleagues in a socialist system if the system were open to investigation, analysis, and discussion.

Discussion: ROY D. LAIRD, *University of Kansas*

Since my first visit to the rural USSR in 1960, major changes have occurred in Soviet agriculture. Farm size has nearly doubled, while rural population has declined slightly. As illustrated in Table 1, production has increased significantly, both in absolute terms and in terms of per capita availabilities.

The advances of the past ten years reflect significant increases in agricultural investment. A guaranteed minimum wage is being adopted by the kolkhozy; farmer incomes have probably doubled; prices paid by the state have greatly advanced. As illustrated in Table 2, more machinery, and much greater amounts of mineral fertilizer are among the important changes in inputs.

Increased investment in agriculture was accompanied by a shift from Khrushchev's heavy reliance for the key crop grain upon the once virgin, but arid, new lands (at the peak some 36,000,000 hectares) to a clear recognition that virtually all future advances must come from greater yields per hectare on the established farming areas. "Intensification" has become the watchword. Grain yields per hectare increased some 30 percent—from 10.2 to 13.2 centners per hectare for all grains and pulses. Further investments in fertilizer, irrigation, etc., will be realized in the 1970's.

Western students of Soviet agriculture have long pointed to the need for much higher investments. However, such specialists also have argued that much of the production problem in Soviet agriculture (especially low labor productivity and low yields) is linked with political (i.e., organizational and administrative) shortcomings in the system. In our opinion such costs may be as much as half the problem, and

Table 1. Production increases, 1966–69 over 1956–60, in percentage[a]

	Grain	Sugar-beets	Potatoes	Meat	Milk	Eggs
Total	31	80	7	44	39	55
Per capita	14	54	−8	25	20	38

[a] Derived from official Soviet statistics, averages for each period; 1970 not available.

Table 2. Key input changes, 1957 to 1967[a]

	1957	1967
Sown area (millions of hectares)	193.7	206.9[b]
Number of farms (kolkhozy plus sovkhozy)	84,100	49,600
Sown hectares per farm	2,300	4,160
Workers (all farms and subsidiary enterprises; millions, 1960 vs. 1968)	29.0	27.5
Sown hectares per worker	7.0	7.5
Mineral fertilizer (millions of tons available)	10.4	33.7
Mineral fertilizer (kgs. per sown hectare)	50	160
Number of tractors (15 hp. units, thousands)	1,635	3,485
Sown hectares per tractor (15 hp. units)	—119	59
Sown area in grains and pulses (millions of hectares)	124.6	122.2
Number of grain combines (thousands)	482	553
Sown grain and pulse hectares per grain combine	254	220

[a] The mid-year of the 5-year planning period, derived from official statistics.
[b] At the peak of the new lands campaign in 1963, the sown area reached 218.5 million hectares.

few or no advances have been achieved here since 1960.[1] The huge farms have become even larger and thus more difficult to manage. For example, although the move to a guaranteed minimum wage has been paralleled by the elimination of the cumbersome old *trudoden* ("labor-day" unit, really a piece-work measure), our questions to farm chairman revealed that the premia scheme (i.e., bonuses for extra work and achievement) still requires each farm to keep track of "thousands" of work norms. Each peasant's performance must be duly recorded daily.

Leonid Brezhnev has not meddled with specific farms and regions the way that Khrushchev did as he repeated the "cult of personality" sin. Nevertheless, Brezhnev's recent speeches have stressed that greater discipline (Party imposed from above) is to be a major key to future advances. The Stalin kolkhozy and sovkhozy were primarily designed as institutions of control over the peasants and their product. (Of course, these institutions also brought the "advantages" of communism to the countryside.) These Stalinist farms remain intact, and neither the new 1970 farm constitution (little changed from the 1935 "model" charter) nor the leadership's pronouncements indicate that any significant changes in the system are in the offing. The farms will remain huge rural bureaucracies; and Moscow will continue to issue its plans and directives, including compulsory deliveries by the farms of the bulk of their produce at set state prices.

My analyses indicate that further production advances from still greater investments alone probably have reached a point of diminishing returns.[2] Moreover, bad crop years will return (such as the one in 1963, which precipitated Khrushchev's ouster). Probably more than one bad year will occur prior to 1980, years that should underline serious faults in the present system. At that time major organizational and administrative changes may be inaugurated, changes that must eventually come.

[1] See especially [1]

[2] This conclusion is documented in our forthcoming "Problems of Communism" article.

Discussion: JAMES S. PLAXICO, *Oklahoma State University*[*]

Soviet farms are very large and involve diverse economic activities, including provision of infrastructure facilities and services such as education, health, cultural, recreational, transportation, communications, and housing. In terms of the U. S. experience, Soviet farms invite comparison with the public *and* private economic activities in a rural MCD such as a township or county.

On both State and collective farms, the State owns the land and there are many small farms (individual plots) within a farm. Personnel on State farms are State employees, while collective farm managers and workers (members) are elected by members. Collective farm workers now receive a fixed wage plus a share of profits.

[*] Oklahoma Agricultural Experiment Station Journal Article 2169, entitled "Impressions of Soviet Farms and Markets."

Comments such as "Russia has no unemployment nor poverty" were heard frequently. It appears that agriculture in the planned economies, as in enterprise economies, serves as a manpower pool. There appears to be a great deal of underemployment in the farm sector. This was particularly evident on a collective farm near Tashkent. On that farm cultural and educational aspects of the farm such as the opera house, the children's music group, and kindergarten and boarding school received unusual emphasis.

In the Uzbek Republic we observed no farming operations in process, only individually-owned livestock and, with the exception of cotton pickers, no farm machinery at close range. The same was true on a large collective livestock farm in Byelorussia. Perhaps livestock, machinery, and labor represent current problems in Soviet agriculture, but tour groups in older agricultural regions saw beef, swine, and dairy operations.

The Hunger Steppe project in South Central Asia may represent some of the best in terms of Soviet planned agricultural development with eventual large-scale State trading in international markets. The project consists of converting one million hectares of uninhabited, salty desert land into irrigated State cotton farms. There are problems, but the evident progress is most impressive. The processing system involving large seed cotton collection-storage stations and year-round ginning could be highly efficient.

Produce of collective and State farms is mostly sold to the State. State receiving, storage, and distribution facilities were not observed. Commodities are apparently traded in these markets at established prices. In farmers' markets, where produce of individual plots is sold, apparently production above the quota from State and collective farms is sold when prices so indicate.

Farmers' markets are apparently most important for fresh meats, fruits, and vegetables. However, a vast array of commodities were being traded in the farmers' markets in Minsk and Tashkent. Officials implied that farmers' markets are an unimportant part of the economy. However, there were indications that governmental agencies systematically collect prices in these markets. The manner in which this information is used in establishing State prices is not clear.

Only limited observations of the input markets were made. However, a State farm manager in the Uzbek Republic gave a price about one-tenth the U. S. price for a two-row cotton picker. The organization of agricultural education and research were not determined, but each farm has a professional staff including engineers, agronomists, economists, and accountants. The role of profits as a performance measure was evident, but conceptual differences precluded an understanding of the Soviet system of accounting.

A first visit to a planned economy proved to be instructive. Progress observed and the impact of priorities on the pattern of progress were impressive. It is clear that there is a role for economists in planned economies and that we should develop a better understanding of Russian agriculture and the agricultural economics profession in planned economies.

Discussion: W. NEILL SCHALLER, *Farm Foundation*

The fourteenth Conference of the International Association of Agricultural Economists, held in Minsk, USSR, was attended by some 700 participants from 59 countries. There were 211 from Western Europe; 203 from Eastern Europe; 120 from Latin America, Africa, and Asia; and 103 from the USSR Soviet interest in the conference was indicated by the fact that there were ten conference applicants for every USSR participant.

Most of the applicants had no difficulty obtaining Russian visas. Through the efforts of IAAE officials a few Israeli economists obtained visas, but visas were denied applicants from South Africa.

As one might expect, there were unique problems of holding the conference in the USSR, due mainly to inflexibilities in the Soviet "system" of handling changes in arrangements. At times it seemed that Intourist had far more responsibility than experience in conference management. However, the Organizing Committee, a separate group, worked hard at minimizing problems and solving those that arose. What each of us expected in the way of arrangements undoubtedly flavored the impressions we brought home.

The Russian papers were criticized in formal presentations and in informal discussions for failing to do more than defend the Soviet

agricultural system. The resulting tension persisted despite some improvement during the conference in the willingness of Soviet participants to at least acknowledge their agricultural problems and to talk realistically about economics. The informal climate afforded by discussion groups undoubtedly helped.

There were suggestions of conflict between younger and older Soviet economists. The younger participants, though relatively few in number, seemed interested in being economists more than "theologians." It is possible that the conference will have a long-run impact on the thinking of younger Soviet economists and, therefore, on the future role of economics in Soviet agriculture. This conflict, along with the criticism of Soviet papers, also might have influenced the thinking of participants from the developing countries and possibly Eastern Europe.

At its business meetings in Minsk the IAAE Council—the governing body of the 1,900-member Association—discussed a range of issues, including the desirability of holding regional conferences on specific topics between major conferences, which are held every three years.

Kenya and Brazil invited the Association to hold its 1973 conference in those countries. The officers will select the site at a meeting in January, 1971.

The Council elected S. R. Sen of India the new president of IAAE, replacing Dr. Nils Westermarck of Finland. Dr. Sen is currently with the World Bank in Washington, D. C. Kenneth Hunt of the United Kingdom was elected vice-president; and Joseph Ackerman, with the Ford Foundation in India, was re-elected secretary-treasurer.

The purpose of IAAE is to foster the development of agricultural economics and its application to the goal of improving agriculture and rural life. The Association provides an unequalled forum for dealing with economic problems within and between countries in a world that grows smaller every day. I left Minsk with a new awareness that the USA is not the only home for competent agricultural economists and innovative research.

ECONOMIC DEVELOPMENT OF AGRICULTURE
(Joint Session, AAEA and AEA)

CHAIRMAN: W. W. McPHERSON, Florida University

Simulation of the Market for Foodgrains in India

HOWARD BARNUM

THE CENTRAL inquiry of this paper is concerned with the effect of the introduction of stochastic terms on the reliability of deterministic conclusions obtained from simulation. Using an estimated market model,[1] two policy questions—the impact of imported surpluses and the management of government stocks of foodgrains—are examined in the context of stochastic simulation. For each policy question three groups of simulation experiments are conducted and the results compared: (1) The model is used in its deterministic form; (2) random disturbance terms are added to the stochastic equations; (3) random disturbance terms are added to particular coefficients.

In the analysis that follows only one aspect of each policy question is examined, and the results are not meant to supply all of the information that would be needed for a policy evaluation. However, the examples shed new light on the two questions and indicate the usefulness of stochastic simulation in the construction of confidence intervals around deterministic conclusions.

The Model

The model consists of nine equations, five of which are stochastic and explain prices, income, commercial imports, area sown, and yield per hectare. Two-stage least squares were used to estimate the coefficients. The estimated equations, over the 17 annual observations for the period 1948–64, are given below. $\bar{R}^2$ is the adjusted coefficient of determination; d is the Durbin-Watson statistic, and SE is the standard error of the estimate. Standard errors of the estimated coefficients are given in parentheses. The five stochastic equations are:

Price equation:

$$(1)\quad \underset{}{PIFG_t} = \underset{(62.6)}{9.69^*} - \underset{(.00062)}{.00153\,DFG_t} + \underset{(2.93)}{2.27\,YN_t^*} + \underset{(.000101)}{.000207\,N_t} + \underset{(.212)}{.421\,PIDS_t}$$

$\bar{R}^2$ = not applicable

$d = 1.80 \qquad SE = 5.59$

where

- $PIFG_t$ is the deflated price index for foodgrains;
- DFG_t is the total quantity (gross) of foodgrains consumed;
- YN_t is the real net national product per capita;
- N_t is population; and
- $PIDS_t$ is a deflated price index of demand substitutes.

Income-generating equation:

$$(2)\quad Y_t = \underset{(484850)}{2469800} + \underset{(11.14)}{70.76\,QFG_{t-1}} + \underset{(.317)}{3.256E_t}$$

$\bar{R}^2 = .98 \qquad d\dagger = 1.46 \qquad SE = 233478$

where

- Y_t is net national product;
- QFG_{t-1} is the gross production of foodgrains in year t-1; and
- E_t is the total central and provincial government expenditure.

Imports equation:

$$(3)\quad MFG_t = \underset{(1337)}{7335} - \underset{(.0224)}{.1287\,X_t} + \underset{(.02626)}{.04630\,BY_t}$$

$\bar{R}^2 = .73 \qquad d = 1.76 \qquad SE = 738$

[1] The model, data specification, and the estimation procedure are discussed in a paper available from the author [1].

HOWARD BARNUM *is assistant professor of economics at Dartmouth College.*

where

MFG_t is the volume of non-PL 480 imports;
X_t is the availability of foodgrains before commercial imports; and
BY_t is a measure of foodgrain import capacity.

Area equation:

$$AFG_t = \underset{(26940)}{27712^*} + \underset{(.2048)}{.4537}\, AFG_{t-1} + \underset{(120.5)}{234.4}\, PIFG_{t-1} + \underset{(387.0)}{900.3}\, T + \underset{(66.5)}{111.7}\, WS^* \tag{4}$$

$$\bar{R}^2 = .92 \qquad d = 1.94 \qquad SE = 2902$$

where

AFG_t is the area sown to foodgrains;
T is time; and
WS_t is a weather index for the pre-sowing period.

Yield equation:

$$ZFG_t = \underset{(.0561)}{.4875} + \underset{(.0000428)}{.0002604}\, F_t + \underset{(.000709)}{.001184}\, W_t^* \tag{5}$$

$$\bar{R}^2 = .74 \quad d\dagger = 1.59 \quad SE = .03079$$

where

W_t is a growing season weather index; and
F_t is an index of fertilizer use.

The model is completed with the addition of four identities defining (1) the quantity of foodgrains given area and yield, (2) demand, (3) the availability of foodgrains before imports, and (4) per capita national product. The identities are

$$QFG_t = AFG_t \cdot AFG_t \tag{6}$$

$$DFG_t = MFG_t + QFG_{t-1} - \Delta GFG_t + MPFG_t \tag{7}$$

$$X_t = QFG_{t-1} - \Delta GFG_t + MPFG_t \tag{8}$$

$$YN_t = Y_t/N_t \tag{9}$$

where

ΔGFG_t is the volume of additions to government stocks; and
$MPFG_t$ is the volume of foodgrain imports under PL 480.

In total, there are 9 endogenous variables and 15 predetermined variables, 3 of the predetermined variables being lagged endogenous.

Four features of the model can be noted briefly. First, lagged area, derived from a Nerlovian adjustment model, is used in the area equation. This was thought to be important for India where there are significant traditional and institutional restrictions on resource allocation. Second, area and yield equations are separated, as was found to be useful by Bernard Oury [3] in his estimation of foodgrain supply in France. The usefulness of this approach for the present model is derived from the divergence between area and yield price responses expected for India. Third, foodgrains, which constitute approximately 27 percent of the total Indian national product, are included as a factor in the income-generating equation. Thus income change is generated not only directly from additional output but indirectly as well through multiplier effects. Finally, the import equation is derived with reference to a planner's welfare function constrained by the availability of foreign exchange. The variable BY is therefore a composite of the value of exported goods plus net capital flows deflated by the price of foodgrains imports relative to other imports.

Application No. 1—the Impact of Public Law 480

Several economists have suggested that the importation of surplus foodgrains under Public Law 480 may have had deleterious effects on the agricultural sector of the Indian economy. The question involves the response of farmers to decreases in foodgrain prices attributable to the imported surpluses. In order to make a thorough evaluation one should know the institutional and structural nature of resource reallocation accompanying diminished agricultural output. But via simulation a tentative answer can be offered to the central questions, what has been the amount of farm output response and what has been the effect on the availability of foodgrains.

Simulation is carried out using the equations of the model described above. The model is structurally recursive, so that once the initial values are given the procedure is to calculate output, pre-imports availability, imports, marketed quantity, income, and price, in that order. Actual values are used for the initial conditions and for the exogenous variables over the simu-

1961	80,369	1,111	2,751	−165	80,813
1962	80,025	264	3,036	−355	84,024
1963	85,830	498	4,198	− 22	84,743
1964	89,426	−786	5,586	−1,243	91,873
Totals	696,435	7,980	28,494		711,491

lation period. The impact of PL 480 is assessed as follows:

(1) The model is run over the period 1956–1964 with the inclusion of surplus foodgrains.

(2) A second run is made with omission of the imported surpluses. That is, equations (7) and (8) are replaced by

$$DFG_t = MFG_t + QFG_{t-1} - \Delta GFG_t \tag{7a}$$

$$X_t = QFG_{t-1} - \Delta GFG_t \tag{8a}$$

(3) A comparison is made of the total output for each run in order to obtain an estimate of the impact of PL 480. The figures for total consumption and commercial imports are similarly compared.

Table 1 gives the results of run 1 (PL 480 included). For comparison, Table 2 gives the results of run 2 (PL 480 omitted). The conclusions from the deterministic simulation are that total output over the nine-year period was depressed by 6,783,000 metric tons; commercial imports were reduced by 2,956,000 metric tons; and consumption was increased by 20,004,000 metric tons.

Added realism and a test of the reliability of the deterministic conclusions are obtained by adding the influence of stochastic terms to the simulation. The stochastic terms are not autocorrelated, have zero covariances and means, and have standard deviations equal to the estimated standard errors. In separate experiments errors are alternatively added to the equations (additive errors) and to the estimated coefficients of the endogenous variables (multiplicative errors).

In both stochastic experiments, the procedure is to take a sample of n simulation runs with the omission of PL 480 and calculate separately, for the totals of production, imports, and consumption: (1) the average value, $\overline{X}$, and (2) an estimate of the standard deviation of the sample means, $S_{\overline{X}}$. Ninety-nine percent confidence intervals are applied to determine whether or not the average sample total is significantly different from the deterministic totals obtained in run 1 and run 2 above. The results for $n = 400$ are given in Table 3.

Several aspects of the experiment results are of interest. Perhaps the most striking result of the experiments is the difference in magnitudes of the standard deviations of sample means for the additive and multiplicative errors. The relatively large size of $S_{\overline{X}}$ for the multiplicative errors emphasizes the sensitivity of the model to changes in the endogenous coefficients. On the other hand, the model is not greatly affected by the additive errors from the estimated equations. Also notable is the fact that the addition of the stochastic terms does not add a bias[2] to the deterministic results; that is, none of the generated totals for the stochastic runs is significantly different from the run 2 totals. Finally, the total simulated production with the inclusion of PL 480 is not significantly less than the production without the surplus when multiplicative errors are introduced. However, the increase in consumption is significant. Thus the results discount the importance of the deterministically calculated impact of PL 480 on output and support the calculated increase in consumption.

Application No. 2—Management of Government Stocks of Foodgrains

It has been suggested [2] that if suitable storage facilities had been available over the

[2] Bias is defined as the difference between the deterministic result and the expected value of the stochastic result.

[a] Production and consumption figures do not tally because production affects consumption with a one-period lag.

period 1951–1964, government stocks of foodgrains could have been regulated so that per capita consumption would have remained constant at a tolerable level while total foodgrain imports were reduced. As with the evaluation of the impact of surplus foodgrains, a rigorous measurement of the net benefits of this proposal would require extensive information. For instance, one would be interested in the cost of storage and distribution versus the cost of a program involving the export of surplus crops during bonus years and importation during drought years.[3] However, the essential aspect of the question—whether or not net imports would have been reduced—can be handled through simulation. It is not sufficient to take the actual output and demonstrate that it would have been redistributed through time in such a way that the desired goals are achieved, because the act of redistribution will in itself affect future output through the price responsiveness of farmers and consumers. To obtain an acceptable estimate of the effect of a stock management program on imports, it is necessary to use a market model.

This, then, is what the following simulation attempts to do: to trace the probable effects of a particular controlled consumption program on Indian foodgrains imports and production from 1952 through 1964. In the simulation program, equation (7) is replaced by

$$DFG_t = N_t \cdot V_0(1 + r)^t \qquad \text{(7b)}$$

[3] After I had substantially completed this project, I learned of the current research of Shlomo Reutlinger. Using a specific demand function with a stochastic element, Reutlinger applies a computer program to calculate the changes in consumer surplus and farm revenue as prices and quantities fluctuate. Adding the net gain (or loss) to the direct costs of storage he derives the cost of a hypothetical buffer stock program. It would be a practicable and, I think, informative task to extend the analysis in this paper in the direction of Reutlinger's experiment [4].

where

V_0 is an initial level of per capita consumption, and

r is the rate of growth of V.

Also, the imports equations (3) and (8) are dropped from the model; instead, imports are determined as the residual quantity that would be required to bring consumption to a specified level should production and stocks be inadequate. If production exceeds the per capita consumption restriction, the excess is used to increase stocks. Any excess output remaining after stocks are filled to capacity is exported.

Setting prices, area, and output equal to their actual values for 1951, the initial level of per capita consumption to 170 kilograms, the rate of growth to .005, and the storage capacity to 4,000,000 metric tons, the market is simulated for the period 1952–64. Results are shown in Table 4, and Table 5 gives the comparable simulation values in the absence of a controlled consumption program. The deterministic conclusion is that it would have been feasible to follow the given path of consumption while reducing total imports over the 13-year period by 37,100,000 metric tons.

Following the same procedure outlined previously, multiplicative and additive errors are introduced, and the mean and standard deviation of sample means are calculated for total imports over 400 stochastic runs. The results are set forth in Table 6.

The stochastically generated totals with the stock program are all significantly different from the deterministic totals under actual policies. However, the average total imports for the stochastic runs with additive errors was significantly different from the corresponding deterministic result (run 2) for the operation of the stock program. This was brought about by the introduction to the model of the decision

Table 4. Simulated values for production, imports, stocks, and consumption under a program of regulated per capita consumption, 1952–1964

[a] Average per capita consumption is .179.

rules regarding the management of stocks and imports. It is relatively easy to introduce errors into either the equations or coefficients of the basic model; to formulate the difference equation for the dynamic model; to take expected values and demonstrate that the bias is zero. However the introduction of the discontinuities or inequalities associated with the decision rules renders the model intractable to algebra. Thus, stochastic simulation is useful in determining the bias when the algebra is cumbersome or unfeasible. For the present model the bias introduced by the stochastic terms is negative and reinforces the deterministic conclusion that reliance on imports would be significantly lowered by the use of the given stock management program.[4]

I was originally attracted to this analysis by the Raj Krishna article cited earlier [2]. Krishna showed that by redistributing the consumption of actual output through time via stocks it would have been possible to maintain a humane overall level of per capita consumption while significantly decreasing India's dependence on imports. The extension of Krishna's analysis to a market model via simulation was straightforward and, as shown above, the model does not contradict his conclusions. However, there are two aspects of the model that deserve attention.

First, the values for V_0 and r used in the example are arbitrary. They were chosen because they were round numbers which allowed both an acceptable consumption path (from a diet viewpoint) and a decrease in imports. Any number of other paths might have been used, but there is inadequate information in the model to choose among them. Necessary considerations in evaluating a given path include the extent of resource reallocation occurring in response to the generated prices, the value of the consumption stream, and the value of released foreign exchange. The ultimate choice would

Table 6. Summary of results of experiments simulating the impact of a controlled consumption program

Type of experiment	Total imports 1952–64		Total production 1952–64	
Actual value	42,963		963,839	
Deterministic:				
Run 1 (no program)	45,333		956,995	
Run 2 (with program)	23,924		963,786	
Stochastic (with program):	$\bar{X}$	$S_{\bar{x}}$	$\bar{X}$	$S_{\bar{x}}$
additive	17,858†	888	964,326	969
multiplicative	20,501	5,925	959,529*	6,406

* Not significantly different from the run 1 value at a 99 percent confidence level.

† Significantly different from the run 2 value at a 99 percent confidence level.

[4] The implications of the analysis extend to the use of an export-import program to maintain the designated consumption stream. The operation of such a program was simulated by setting stock capacity to zero and conducting the experiments described. The results were very similar to those presented in Tables 4, 5 and 6. A choice between the stock management and the export-import programs would be facilitated by a cost-benefit analysis such as that mentioned in footnote 3.

depend on political feasibility and a planner's conception of community welfare. It is certainly possible that under either of these criteria a path might be chosen that would not result in a decrease in imports.

Second, any intertemporal redistribution program that lowers dependence on imports will by definition also lower average per capita consumption over the program period. Given the distributional problems in India, it is doubtful that a slight general lowering of the average per capita consumption level would be shared equally by the populace. Instead, without offsetting government action the top income groups would maintain consumption, with consumption per person being increasingly affected in inverse proportion to income. Thus the implementation of a controlled consumption program implies the simultaneous implementation of a plan to encourage an equitable distribution.

Summary

A simulation model of the market for foodgrains in India has been applied to two policy questions. With regard to the first question, simulation indicates that the import of 28,000,000 tons of PL 480 foodgrains over the 1957–1964 period depressed slightly the path of production and increased markedly the path of availability. With regard to the second question, simulation indicates that, assuming suitable storage facilities, government inventories could have been regulated over the 1952–1964 period so as to maintain a growth of .5 percent per year in per capita foodgrain consumption from an initial level of 170 kilograms while substantially decreasing total imports over the simulation period.

For each policy question, the stochastic experiments, although producing markedly contrasting paths, substantiated the general results. It was found that the policy conclusions from the deterministic simulation are significant, with the introduction of additive random terms having a standard deviation equal to the standard error of the estimated equations on which the model was based. However, the model is highly sensitive to the introduction of multiplicative random terms, and the simulated depression of production with PL 480 was not significant in the multiplicative experiment. In addition, it was found that the expected value of total net imports under the controlled consumption program was significantly less, compared to the deterministic total, with the introduction of stochastic terms.

The Transformation of Traditional Agriculture: A Case Study of Punjab, India*

I. J. Singh

THE PURPOSE of this paper is to report the results of a dynamic regional model of agricultural production response, developed and applied to traditional agriculture, which (1) is based on the already tested notions of economic rationality and price responsiveness in traditional agriculture; (2) incorporates several categories of response forces already studied in the case of developed agriculture; and (3) includes in an essential way the features of subsistence production and household-firm interdependence that are central to the study of production response in traditional agriculture. Specifically, recursive linear programming and activity analysis are used to analyze and simulate the production, consumption, and investment decisions of subsistence farmers in a given region. The result is an improved understanding of the process of agriculture in transition and an operationally tested method for projecting future development.

There is growing evidence of the recent transformation of the agricultural sectors of such diverse economies as Israel, Nigeria, West Pakistan, India, the Philippines, Tanganyika, and Thailand [18]. These vast agricultural transformations offer an excellent opportunity to enhance our understanding of the process of development. The purpose of this study was to investigate some of the factors and conditions responsible for one of these transformations, not in its generality, but in great detail.

While agricultural development remains at the center of development theory and policy, only recently has attention been given to the empirical investigation of its role in the LDC's. Though some investigations stress the importance of agricultural exports as a point of departure in the LDC's, the more fundamental problems are those associated with agricultural production response, since agricultural exports, whatever their role, cannot increase without an increase in agricultural production.

A large part of the empirical work done so far on production response in the LDC's touches on a very important aspect: whether peasants in traditional or near-traditional agriculture respond to market opportunities. These studies have shown that agricultural production of specific commodities in specific LDC's is price responsive, especially when account is taken of adjustment lags due to uncertainty and the quasi-fixity of capital stocks. They show that the form and direction of this response is consistent with price theory, so that we can expect market incentives to play an important role in the transformation of traditional agriculture. These empirical findings clearly refute those who believe that cultural and institutional restraints limit to insignificance any responsiveness to market incentives and that the accepted notions of "economic" behavior cannot be applied to traditional agriculture.[1] This study shows that it is possible to explain production response in traditional agriculture within the accepted framework of economic rationality.

There are many detailed elements of production response that have already been incorporated in regional production models. Among these are the interdependence of outputs using common inputs, technological change, changes in yield and acreage components in crop production, uncertainty and adjustment over time, the relative interaction of inputs and output prices, the rates of investments in factors fixed in the short run, the aggregate supply of production inputs, and planned or programmed policy actions [2, 4]. The relevance of these factors for the study of production response in traditional agriculture has not been fully appreciated. It is one of the purposes of this study to correct this shortcoming. In addition it incorporates features of traditional agriculture: "subsistence production" and the critical household-firm interdependencies, a recognition of which is necessary to give a complete picture of production response in traditional agriculture.

* The research for this paper was supported by the Agricultural Development Council and the National Science Foundation under grants to Richard H. Day of the University of Wisconsin, to whom I am indebted for his continual support.

I. J. Singh is assistant professor of economics and agricultural economics at Ohio State University

Activities of a Subsistence Production Farm

The notion of subsistence production

It has long been recognized that the farm combines two fundamental units of microeconomic activity, the household and the firm. The resulting interdependence has been analysed for developed agriculture [2, 5, 10]; but while this is clearly of the essence in the analysis of traditional agriculture, its implications, with a few exceptions, have not been understood. Traditional agriculture is distinguished by the predominance of farms whose main characteristics are (1) the dependence of the household upon the output of the farm to maintain family and animal labor and (2) the dependence of the farm upon the household for its labor requirements. The former determines the degree of subsistence production (commercialization), that is, the proportion of production consumed or sold by the farmer; the latter, the degree to which a farm is a family farm, that is, the proportion of family (or hired labor) in the total labor input on the farm [13].

This interdependence has several implications: (1) Production and consumption decisions are interdependent, since subsistence requirements modify cropping patterns, prevent specialization, and affect the amount and composition of the marketable surplus, thereby dampening response to market profitability; (2) consumption and investments decisions are interdependent since the former, through savings and the marketable surplus, affect cash flows and determine the latter; (3) the availability of family labor plays an important role in the choice of technique, thus determining the composition and amount of investment and the path of technological change. These considerations suggest that in the study of production response in traditional agriculture, an appropriate starting point for analysis is the activity of the subsistence production farm.

The farming household in traditional agriculture can be said to be engaged in a number of general economic activities throughout the year, such as purchasing, production, consumption, sales, investment, and financial activities. These include "traditional" as well as "new" activities which we wish to consider for analysis. Let us examine these activities in greater detail.

Purchasing activities

Purchasing activities include the use of hired labor, animal draft, and tractor hours on the farms in the region. These activities are associated with the use of variable inputs, which may be purchased but are not likely to be unless near-perfect owned substitutes are exhausted (as in the case of labor), or with the use of owned inputs that require complementary cash inputs for their use (as in the case of tractors and animal draft). The use of these inputs depends upon (1) their relative prices, (2) their relative productivities in the alternative uses, (3) their aggregate regional supply, and (4) the availability (existing capacity) of owned substitutes.

Production activities and technological change

Production activities are those that transform owned and purchased inputs into outputs and are measured in acreages sown to important crops in the region. They include: (1) crops grown during two seasons in the cropping year —Rabi (winter) and Kharif (summer); (2) crops grown on irrigated and unirrigated soil conditions; (3) both traditional and new high-yielding crop varieties; (4) crops grown for fodder purposes; and (5) production under two technologies for each crop activity—traditional (bullock-operated) and modern (tractor-operated). These production activities use variable inputs, quasi-fixed capacities, and land of different qualities, and yield final crop outputs measured in yields per acre.

Since crop production is carried out by the performance of agricultural tasks, these are represented by "intermediate production" activities in the present model. Each intermediate production activity has associated with it the use of various inputs, the cost of performing a standard unit of a task, and an intermediate output of a unit of the standard task. The production of final crop outputs then involves the use of several intermediate task outputs by the production activities.

Intermediate production activities provide a quantitative dimension that allows us to view technological change as incorporating (1) the inclusion (or exclusion) of certain agricultural tasks, (2) a change in the way in which tasks are performed, and (3) a change in the level of input use by the tasks. In this manner it is possible to examine the impact of strategic inputs such as water (through irrigation task activities); inorganic fertilizers (through fertilizing activities); the use of new power sources (by incorporating the different ways in which task activities produce intermediate outputs); and the adoption of new high-yield varieties (by considering

them as separate production activities).[2] The process of technological change is viewed not as a replacement of a traditional technology by a new, modern technology but as a task-by-task choice by farmers in the region over time.

Another crucial feature that has to be incorporated is the seasonal use of various inputs, since agricultural operations are time inelastic. A given input available at two different times of the cropping season has to be considered as several different inputs. This feature is included by giving the purchasing activities a time subscript and considering labor, animal draft, and machine capacities during different periods in the cropping year.

Consumption activities

Consumption activities incorporate the nature of subsistence production in terms of the amount of foodgrains and partly processed outputs (sugar) retained for consumption by the household and fodders planted for the maintenance of livestock and draft animals. These consumption requirements are exogenously estimated[3] and are viewed as a constraint in terms of the minimum amounts of certain final crop outputs that have to be grown in any region. Consumption activities have no direct costs, but have opportunity costs in terms of possible profitable crop outputs foregone.

Investment activities

Investment activities are associated with investments in quasi-fixed inputs leading to the replacement and additions to the capital stock. They consist of the purchase of new power sources whose profitability is based upon a net cost calculated on a payback principle [6]. Investments then become profitable if additions to capacity generate enough cost savings in terms of the production or intermediate production activities that use these capacities. Investments also involve a cash outlay for their purchase.

Sales and financial activities

Sales activities involve the sale of marketable surplus for cash when outputs are sold at harvest prices. The cash generated from current sales is then available to meet jointly the requirements of activities in the following year. The decision to sell is viewed as the outcome of two decisions, the decision to produce and the decision to consume out of production with no inventories other than those in the form of crop outputs retained for annual consumption.

The financial activities include (1) a banking activity that allows farmers to "save" excess cash available over cash used at a nominal interest rate which is then available with the accrued interest in the following year and (2) a borrowing activity that allows farmers to borrow working capital at the going interest rate, which then has to be repaid along with the accrued interest in the following year. Other financial cash transactions such as nonfarm cash incomes and cash expenditures for consumption are estimated exogenously and are added to or subtracted from the cash available for the following year.

These activities are incorporated in a recursive programming framework in which decisions are presented as maximizing an objective function each year, subject to a set of constraints that partly depend upon previous year's decisions. The next two sections briefly describe the objective function and the constraint structure.[4]

The Objective Function

The subsistence farmers in a relatively homogeneous farming region carry out their activities with two ordered objectives in mind, the foremost objective being to meet family requirements for food and animal requirements for fodder; once these have been met, to minimize short-run cash costs. This decision rule differs from that of a firm minimizing cash costs in three instances: (1) The first-order consumption requirements act as a constraint upon cost minimization; (2) the use of family labor is given a zero cost in the function, its annual costs of maintenance being fixed; and (3) the use of animal draft includes only variable costs (concentrates and additional fodder given when animals work), since annual maintenance costs are also fixed.

The cost coefficients for the objective function include the variable cash costs for labor hired (if any), tractor hours used (fuel and other costs), and animal draft used (variable cash costs) for the purchase activities; the costs

[2] For a detailed exposition of the notion of intermediate outputs, standardized agricultural tasks, and technological choice, see [17]; to see how these are incorporated into a regional programming model, see [16].

[3] The main determinants of the consumption of subsistence crops were found to be the size of the household and the amount of the output of the crop [15].

[4] For a detailed exposition of the model, see [16].

of seeds and manure for the final production activities; the costs of performing a given standard task for the intermediate production activities; costs estimated on a payback principle for the investment activities; harvest prices of crop outputs for the sales activities; and the appropriate interest rates for the savings and borrowing activities—all lagged one year to represent simple price expectations on the part of the farmers.[5]

The Constraint Structure

The constraint structure includes three broad categories: (1) resource constraints, (2) behavioral constraints, and (3) financial constraints.

Resource constraints

Resource constraints include constraints upon the regional availabilities of (1) variable inputs such as family labor, hired labor, fertilizers, and animal draft; (2) quasi-fixed inputs in the form of available capacities of various power sources such as tractors, tubewells, threshers, cane crushers, which change with both investments and physical depreciation; and (3) fixed inputs of various qualities of land and the amount of canal irrigation available in the region.[6] The strong seasonal use of inputs is accounted for by considering labor, animal draft, and quasi-fixed capacities during seven different periods in the cropping year, while land and canal irrigation availabilities are considered for the summer (Kharif) and the winter (Rabi) cropping seasons.

Behavioral constraints

Behavioral constraints describe the elements of response to uncertainty, adjustment through time, adoption, and learning behavior that modify the response to economic opportunity, and include three broad categories: (1) flexibility constraints, (2) adoption constraints, and (3) consumption constraints.

The flexibility constraints place both an upper and lower limit on the extent to which subsistence farmers are willing to change their output of any given crop in response to profitability in any one year. This cautious response to changes in profitability may be due to (a) expectations that the changes may be short-lived; (b) a desire to diversify crop portfolios to avoid risk, given the nature of subsistence. Flexibility constraints express the farmer's response to risk and uncertainty and can also be viewed as an approximation of a nonlinear objective function in a linear model.[7]

The adoption constraints account for the fact that when a new activity is introduced, even if it is profitable and remains so, it is not adopted immediately. Both the investment in new power sources and growth in the acreage of new crop varieties are constrained by an upper limit to express factors such as learning, experience, cautious behavior, and innovative leadership. The adoption constraints describe an s-shaped path and depend recursively upon the previous year's level of adoption. Such adoption paths are not peculiar to traditional agriculture but are also evident in modern agriculture and industry [6, 11].

The consumption constraints describe the limitation imposed by the need to produce family and livestock requirements on a subsistence farm and are included in the form of lower constraints upon the amount of output for certain crops.[8] These consumption constraints are peculiar to subsistence agriculture and limit specialization and response to market profitability.

Financial constraints

Financial constraints are of two types: (1) an upper limit upon the total amount of short-term working capital available from various sources and (2) the constraint upon cash available for carrying out the activities that use cash by the total cash generated in the previous year through sales, savings, and nonfarm cash incomes, less any cash consumption expenditures and the repayment of previous years' borrowings of working capital.

Model Summary

The model is computed by setting up a linear programming problem for a given initial year and a solution that maximizes the objective function obtained. The results from this solution are then used to estimate a new set of con-

[5] The use of a more complete price expectation model is also possible and is under investigation.

[6] Canal irrigation is an example of fixed regional resources available to farmers that can be changed by policy decisions with regard to infrastructure.

[7] For the use of flexibility constraints, see [4], [12], and [14]; for a theoretical justification of their use, see [3].

[8] This is only one way to include subsistence production. An alternate formulation involving a recursive dependence on endogenous levels of outputs and incomes generated by the model is being investigated.

straints for the objective function, constraints that depend recursively upon the previous year's decisions; and along with exogenous information on input and output prices, the problem is set up for the next year and new objective function maximized. Certain activities and constraints are introduced only when they become available to farmers in the region (such as new varieties, inorganic fertilizers, and new power sources).[9]

Summary Results for Central Punjab, India (1952–1965)

The tremendous growth during the past two decades in total output and productivity in East Punjab (India) and especially the central five districts—Central Punjab—has been widely and repeatedly reported [7, 8, 9]. What has not been reported are the tremendous structural changes that have accompanied this growth and have slowly but surely transformed the traditional agricultural economy. The r.l.p. model described here has made it possible to explain precisely this structural transformation in terms of the economic variables and the environmental conditions that operate at the farm level.

During the 14 years for which the model was computed, four aspects of this transformation are clearly delineated: (1) investments in new power sources; (2) the consequent change in farm technology; (3) structural shifts in labor use; and (4) commercialization of the subsistence production sector. These results are now briefly reviewed.[10]

Investments in new power sources

The traditional inputs of peasant agriculture, labor and animal draft, are being complemented by the use of new power sources. Tremendous investments in tractors, tubewells, and power threshers are predicted by the model and are partly shown in Figure 1. According to the model, the number of tractors in use has increased sevenfold, the number of tubewells in use nearly twelvefold, and the number of threshers over fourfold, even though the last were introduced only in 1963. Investments in power cane crushers increased between 1952 and 1955; but no additional investment occurred again until 1959–60, after which investments again fell to zero. The index of use showed a similar trend, with an increase in the first three years followed by a continual decline almost to zero by 1965. This indicates that the adoption of labor-saving power sources has not been across the board and that in some cases their use has actually declined. This has a bearing on the choice of technique, since power cane crushers are profitable to use only when labor has to be hired during the period of cane crushing (November to March). With the growth in population and availability of family labor and a decline in the total amount of cane crushed, there has actually been a reversal in the adoption of labor-saving technology and the mechanization of this task.

Change in farm technology

The investments and the use of new power sources predicted by the model show that the trend in mechanization does not lie on a balanced growth path. The choice with regard to technique is made task by task. During the period studied, this choice led to an investment pattern oriented towards the performance of specific tasks—tractors for land preparation, sowing, and transportation; tubewells for irrigation; and threshers for threshing.

Figure 1 shows the indices of total gross area sown, and Figure 2 shows total standard units of land preparation, irrigation, cane crushing, and transportation used in the region, and the indices of the performance of these tasks by labor-saving technologies along with the percentage of the total task use mechanized (1952 is the base year).

The index of the total gross area sown has increased by 37 percent in the period, but the index of area sown by tractors has increased by 363 percent while the percentage of total gross area sown by tractors has increased from 7.7 percent in 1952 to 25.6 percent in 1965. The indices of total land preparation, irrigation, and transportation increased by 46 percent, 39 percent, and 396 percent, respectively, while the indices of the performance of these tasks by mechanized means increased 384 percent, 501 percent, and 336 percent, respectively. The percentages of land preparation and irrigation performed by mechanized means increased from 11.3 percent to 37.3 percent for land preparation and from 15.8 percent to 68.3 percent for irrigation from 1952 to 1965, in the latter case totally replacing the traditional Persian wheel as a means of irrigation by tubewells. The in-

dex of total cane crushing declined, as less sugarcane output is being processed on the farms and more being taken to sugar mills; but the percentage of cane crushed by diesel declined from 35 percent in 1954 to 5.2 percent in 1965.

To summarize, the pattern of change in farm technology predicted by the model indicates that technological change is task oriented; that it does not consist of the total replacement of a traditional technological set (bullock-labor intensive technology); that it consists rather of

a task-by-task replacement leading to a period of transition during which labor-saving and labor-using technologies continue to be juxtaposed in a "hybrid technology" whose components depend upon the detailed cost structure of operations and whose proportions change over time.

Annual and seasonal labor use

Figure 3 shows the index of total annual labor use predicted by the model along with labor use in selected periods of the cropping year. Total labor use declined from 1952 to 1961, during a period of growth in output due to the adoption of labor-saving technologies, but has shown some increase from 1962 to 1965 because of an increase in total output at an even higher rate. Annual labor use as a percentage of total labor available declined from 63.4 percent in 1952 to 48.6 percent in 1962, but increased to 54.4 percent by 1965. Similarly, annual labor use as a percentage of family labor available declined from 82.2 percent in 1952 to 63 percent in 1962, but increased to 70.5 percent by 1965. Using the often misused measure of "labor surplus" on the basis of annual availabilities, anywhere from 52 to 36 percent of the total labor and 37 to 17 percent of the family labor is "surplus" in the region. The problem with this measure is that it does not take account of the seasonal distribution of labor use.

When labor use is examined during different periods in the cropping year, the model projects a far different picture. The index of labor use increased substantially for some periods (during the periods of summer land preparation and planting, winter harvesting, and transportation), increased only moderately in others (during the period of summer irrigation and winter planting), but declined substantially in others (during the periods of summer harvesting, winter irrigation, and sugarcane harvesting and processing), even though total output and acreage sown increased substantially. (Figure 2 shows indices for period V (winter irrigation) and period VI (winter harvesting) and for total annual labor use.)

If we examine seasonal labor use in relation to total and family labor availabilities, we do not get the same results as those predicted by annual labor use. The model shows labor is "very scarce" in some periods, "occasionally scarce" in others, "slack" in some, and "very slack" in others, when measured in terms of the amount of family labor available in any period. In periods when labor is very scarce and family labor is exhausted, labor has to be hired in order to perform the tasks. This seasonal scarcity explains in part why technological change is task oriented and why mechanization occurs in an apparently labor-surplus economy. Though the demand for total labor has increased only slightly, changes in the cropping patterns and the technological mix have brought about a structural shift in the demand for labor in the region. Not only have seasonal labor shortages brought about technological change in some cases, but in its turn technological change has allowed an increase in total output and resulted in an increase in the demand for labor in some periods that would otherwise not have been possible. In the period of transition, mechanization per se does not imply a reduction in the demand for labor.

The commercialization of traditional agriculture

The growth in total output and productivity in the last two decades, which has been accompanied by increasing mechanization, changes in farm technology, and structural shifts in the demand for labor, has also been accompanied by an increasing commercialization of the agricultural sector and a shift away from subsistence production. This increased participation in the market economy is predicted in the model by (1) an increase in both the amount and the percentage of the marketed surplus for major crops in the region and (2) an increase in the use of nonfarm inputs.

Figure 3 gives the indices of total production, marketed surplus (sales) and consumption of wheat and sugarcane from 1952 to 1965 predicted by the model.[11] The index of the production of wheat increased by 14 percent and the index of sales increased by 273 percent, while the index of the consumption of wheat remained fairly constant. The marketed surplus of wheat as a percentage of total production increased from 53.4 percent in 1952 to 80.3 percent in 1965, indicating that whereas 47 percent of the production of wheat was for subsistence in 1952, only 18 percent of the production was for the same purposes in 1965. The predicted results for sugarcane are more dramatic, for while the index of production increased by 138 percent,

[11] The model included all major crops in the region—wheat, gram, barley, winter fodders, maize, rice, groundnut, cotton, millets, and sugarcane.

the index of sales increased by 336 percent, the percentage of sales to total production increased from 45.5 percent in 1952 to 83.5 percent in 1965, and the percentage of subsistence production dropped from 55.5 percent to a bare 16.5 percent—a tremendous shift towards production for the market. The index of consumption of sugarcane in the form of processed gur (brown sugar) actually declined from 100 in 1952 to 72 in 1965, showing a substitution of factory sugar in the diet. Similar results were predicted for all the major crops—maize, rice, groundnut, and cotton (American).

With an increase in the use of tractors and diesels as power sources, the total consumption of diesel fuel increased nearly five fold from 11.4 million litres in 1952 to 55.5 million litres in 1965 (Figure 3). At this rate of growth in consumption, in the years to come the availability of petroleum products could act as a serious constraint upon the adoption of these power sources, since India is short on petroleum resources and has to import them.

Another component of the increased use of nonfarm inputs predicted is the increase in the consumption of nitrogenous fertilizers, whose consumption increased twelvefold (Figure 3) from a mere 1.6 million kilograms of nutrient equivalents of nitrogen in 1957 to 20.4 million kilograms in 1965; and the demand is insatiable at currently subsidized prices, with the increased adoption of new varieties and increased use of water. The model showed that the only constraint upon the use of nitrogenous fertilizers was their total availability.

Conclusions

These substantial structural changes in investment patterns, farm technology, labor use, and market orientation predicted by the model, along with the unprecedented increases in total output, have spelled the content of the green revolution in the Punjab. The model is based on the assumption of rational economic behavior and uses the standard tools of economic analysis to generate the past development of the agricultural sector in a selected region, and is able to explain observed phenomenon of the transformation process. It is reasonable to expect that the model will also be capable of projecting possible future transformations under alternative policy assumptions.

The Green Revolution and the World Rice Market, 1967–1975*

E. Ray Canterbery and Hans Bickel

The dramatic green revolution in rice, wheat, and corn may shift economic development problems from concern with widespread starvation to concern with a potential grain glut on world markets. This unexpected technological twist foreshadows possibly some new trading difficulties for developed agricultural exporters such as the United States, Japan, and Canada plus some entirely different kinds of problems for LDC grain consumers and producers. The history of the development of the new seeds and the precise nature of the new technology has been widely discussed elsewhere (see, e.g., [1]). Barring widespread war, one realizes that what happens in terms of LDC production of rice and wheat and developed nations' responses will for the most part determine the economic destiny of the less developed world in this decade.

Methodology

Because of the sharp change in technology, many official government forecasts for grain output and trade patterns through 1975 are in error. The purpose of this paper is to attempt to remedy these difficulties by taking *explicitly* into account the yield changes from the technological advance and the impact of both production and consumption changes on the price of rice in the major producing nations and in the world.

Rice consumption and production estimates were developed both from statistical equations and, in the case of production in the miracle-grain-adopting nations, from nonstatistical techniques.[1] It was possible to estimate statistically rice demand functions for the major consuming nations and for the world because of the stability of most of the consumption functions. Two sets of equations were run for rice consumption (C_r) for each of the major nations: (1) Explanatory equations meeting relatively high statistical standards were estimated for the purpose of calculating income and price elasticities; (2) forecasting equations were developed that met only the test of "best fit." The same criteria were applied to production estimates.

The estimation for production and related elasticities was more difficult. We were in part constrained either by data availability or by the research costs of building data series for all the potential determinants of output. We were able to develop data series on total fertilizer consumption (F), total production (Q), area in hectares used in rice production (A), and various price series for 1955–1966, the period used for the regressions. We knew that irrigation expansion, labor input growth, insecticide usage, and rainfall variation would in some cases strongly influence output. As it turns out, the "package" nature of the miracle grain technology causes fertilizer usage, irrigation, and insecticide use to increase at about the same rate. In addition to their reduced sensitivity to the length of days and their early maturity, the new varieties experience diminishing returns from fertilizer application at much higher yields than the old, local varieties. Hence, the effect of the new technology can for the most part be "embodied" in fertilizer consumption in the LDC's. This of course is not true for the DC's. In the nonequation estimates of output in miracle-grain-using nations it was possible to take into account most of these factors.

The countries individually selected for both rice consumption and production analysis are those that are currently important in terms of quantities produced and/or consumed plus those having substantial potential. The statistically used consumption definitions by country depend upon the nation's rice trade balance during the observed period. For the importing nations of India, Japan, the Philippines, and Malaysia, consumption equals production plus imports. For the exporting nations of Burma, Thailand, Brazil, and the United States, consumption equals production minus

exports. South Korea and Pakistan are intermediate cases, while West German consumption equals her imports. Because of data limitations, one important nation is excluded—Mainland China—while only consumption estimates were made for Indonesia and Vietnam. Mainland China and Indonesian consumptions are discussed in terms of UNFAO projections.[2]

There is not sufficient space to detail herein all the econometric designs for the statistical estimates.[3] A formal theory of expected relations was postulated prior to conducting the final empirical tests. It was hypothesized that rice consumption is related to income, prices or relative prices, and population. Because of multicollinearity, it is necessary to combine GNP and POP into one variable in the *explanatory* equations. In addition to linear forms, log, inverse log, and semilog transformations are used to capture the actual pattern of behavior of the variables over time. A dummy variable is used for extreme observations or large function shifts. In the world equations, for example, a dummy variable is used for the 1958 dependent variable observations which apparently were affected by the Suez crisis. (Overall, the dummy variable is used sparingly.) In all consumption equations the *current period* price is used. In a few cases in which multicollinearity was biasing the "explanatory" coefficient estimates, the nominal (P_r) rather than the relative (or real) price (P_r/CLI) is substituted. In most of the LDC's there is no identification problem with price, as output depended upon price lagged. There was, however, a price-simultaneity problem in Japan and Thailand, and a simultaneous solution was required.

Preliminary statistical tests suggested a high correlation between area and fertilizer consumption in most nations. Also, in tests with these two variables and relative price (lagged one year) against Q_r, the price variable was usually statistically insignificant. A number of random variables, weather variation being one, influence agricultural output. In part this explains the often low degree of linear correlation between output and time. There is also a lag between commodity price changes and changes in output, because it usually takes a new growing season for commodity price-induced input changes to affect production. This lag is sometimes shorter in developed nations and will become shorter in the LDC's as the area that is doubled-cropped increases. As a result of these considerations both current and lagged observations of the independent variables appear in the production equations; area and yields usually are estimated in separate equations, and subsequently their estimated values are multiplied $[\hat{A}_r \cdot (\hat{Q}_r/\hat{A}_r)]$ to gain production estimates. As (Q_r/A_r) involves a function of a function, two-stage least squares (2SLS) is used in estimating yields. This specification has the further advantage of avoiding biases from multicollinearity resulting from the necessity of leaving out correlated variables.

Where no identification problem exists (price lagged in production equation), the explanatory price parameters are estimated directly by classical least squares. Then elasticities, with price as the dependent variable, can be determined by solving for price in each set of supply-demand equations. However, in those nations where both current supply and current demand determined price in an identified model, a simultaneous estimation is used. The reduced forms of these equations can be derived by solving the equations simultaneously in terms of P/CLI and in terms of C. The statistical parameters can then be estimated indirectly from the reduced form equations. Where the equations are simultaneous and not perfectly identified, we use 2SLS in estimating parameters.

The reliability of the elasticity estimates (from "explanatory" equation estimates) is not affected by multicollinearity but possibly is affected by small sample sizes. The standard errors are not biased by autocorrelation, but elasticities are biased where derived from nonlinear equations. The direction of bias from the latter source cannot be determined, but because of the "ball park" nature of the estimated elasticities the errors are believed to be relatively small.

Statistical forecasts of production at 1966 prices lead to underestimated output values in those nations adopting the miracle seeds after 1966. In such countries nonequation production estimates are initially made at assumed 1966 prices. The final projections "marry" the statistical forecasts, the elasticity estimates, price changes, and the nonequation forecasts of production.

Forecasting production and consumption at varying prices is of course most difficult; and for some nations such forecasts are not possible

[2] A summary of data sources follows: production and area, [2, 3, 4]; trade, [6]; prices, [2, 3, 5]; fertilizer, [3]; stocks, [7]; GNP, [8]; population, [7].

[3] These details also are available upon request, pending their publication.

because of unreliable price elasticity estimates. Only price-constant forecasts are provided for such nations. The process whereby estimated input-price and consumption-price elasticities are applied to the price-constant forecasts is explained in a later section.

Limitations of Purely Statistical Estimates

The listing and evaluation of certain assumptions that apply to our statistical forecasting equations perhaps describe best the limitations of the statistical part of this study.[4] In certain cases the least-squares estimates were adjusted "by hand" to account for known divergencies between the statistical path and the actual path of the dependent variable. For example, where per capita consumption has reached a "maximum" level in DC's during the estimation period, the consumption equation tends to overestimate projected consumption.

It is assumed that:

(1) The usual least-squares assumptions apply to the *initial* forecasts from the equations. Of course, the main divergence from the least-squares path for production is expected to be caused by the adoption of new technology, and this is taken care of in the nonstatistical estimates for those countries in which it is expected.

(2) Unless otherwise specified, any extremely adverse weather conditions dominating any particular year will be offset by extremely favorable weather conditions in some other year.

(3) The prices of nonlabor inputs averaged during the forecasted period values are equal to their observed averages. Because of more intensive cultivation of land in the IRRI-adopting countries, the long-run price of capital may rise relative to the price of land and labor. Such relative factor price changes, however, are not expected to have any appreciable impact prior to 1975.

Labor costs are in part accounted for in the cost-of-living index used as a commodity deflator. Hence, changing labor costs are in part taken into account in the nonconstant price forecasts. Although the new varieties are both labor- and capital-using, they are at the margin more capital-using than labor-using.[5]

(4) Labor inputs will grow at a sufficient rate to allow the expansion of the implied potential associated with land, capital, and technological availabilities.

(5) The rate of double-cropping of *local* varieties will not change through 1975. This is highly probable, as double-cropping normally can occur only on irrigated land and most of the new irrigated land will be devoted to the new higher-profit miracle grains. This potential increase in double-cropping is taken into account in the nonstatistical estimates.

(6) There will be no major war in the Far East or Southeastern Asia prior to 1976.

(7) Increases in irrigation are either proportional to the increased area cultivated or are highly correlated with a time variable.

(8) Mechanization has not had a significant impact on rice production.

(9) Current aid, government programs, and policies affecting agriculture and trade in rice in all nations will not change. *This assumption, however, can be relaxed when we make a choice between estimates of production at the various assumed price changes.*

Estimated Price Changes and Production Behavior

Price data

The most frequently used price for both the demand and the supply equations is the milled wholesale price of rice, which in most cases is highly correlated with the retail price. It is believed, however, that in many cases the milled wholesale price may generate better statistical results with the supply equations than with the demand.[6] In all cases "free market" prices are used; that is, the price series selected for each nation is one of varying nominal prices. Beyond this the selection criterion is one of data availability.

In constructing real prices, we divided the nominal price by a cost-of-living index (CLI), an agricultural retail price index, or an agricultural wholesale price index. In some cases there was very little difference in the results irrespective of which index was used, but in general the cost-of-living index gave the best statistical results in both the demand and supply equations. Consequently, the cost-of-living index is used in the final estimating equations.

[4] The extra nonstatistical assumptions are also available upon request, with the nonstatistical tables.

[5] Over time, of course, this increased relative demand for capital may increase the price of capital and in the longer run may moderate expansion of IRRI 8 production.

[6] The following exceptions apply: the husked producer price is used for Japanese production *and* consumption; paddy producer for U. S. supply; paddy wholesale for Thailand and Brazilian supply; the export (to Ceylon) price for Burmese demand and supply; and the averag unit value of export for world production-consumption.

Table 1. Estimated rice consumption elasticities from structural equations[a] (at 1966 observations for nonlogs)

Nation	With respect to C_r				With respect to C_r/POP	
	GNP/POP	P_r/CLI	P_r	GNP	GNP/POP	P_r/CLI
Japan	.107	0				
United States				1.98	0.86	0
India	1.33	0				
Pakistan	7.14	3.85				
Thailand	−3.96	0				
Burma	−3.46	0	−4.40		−6.42	−3.68
South Korea	1.15	0				
Philippines	4.00	0				
Malaysia	1.27	−.89				
Brazil	2.47	0				
West Germany			0	.89		
World total	1.00		−0.50[b]			

[a] The algebraic signs of the elasticities are taken from the signs of the slope coefficients; hence a positive sign for price suggests perverse elasticity. With the exception of Pakistan, all estimates are based on equations having statistically insignificant multicollinearity. Where the price coefficient is not significant and other statistical requirements are met, perfect inelasticity is inferred.

[b] This elasticity is with respect to the world *trade* (unit value of exports) price.

Price-change estimates

Although production and consumption elasticities can be estimated from the structural explanatory equations, the current period price of rice itself is an endogenous variable, being determined simultaneously by output and consumption. Therefore the impact of the same independent variables on the price of rice is estimated by solving the supply and demand equations simultaneously for current price (except where an identification problem exists). The structural elasticity estimates appear in Tables 1 and 2; the simultaneous estimates appear in Table 3. These structural and simultaneous elasticities (where reliable) provide sufficient information to estimate price changes and subsequent production and consumption adjustments from their 1966 constant price values.

The simultaneous price elasticities are based on "final" production and consumption adjustments that have occurred as prices change. In some years in some countries the nominal price of rice is fixed at a support level for the producer or at a ceiling for the consumer. But as we move from price elasticities to estimates of price changes in those nations using government market intervention, these are the price changes that will occur as such price supports or ceilings are removed. It is of course possible and *even probable that the governments' prices will not be removed prior to 1975. In those cases the constant-price production forecasts apply.*

Forecasts of the independent variables through 1975 were made in order to estimate price changes. The "free market" estimates in Table 4 are derived by multiplying the expected annual percentage change in the independent variables—per capita income, area, fertilizer, lagged price—by their respective simultaneous elasticities with respect to current period price (from Table 3). The lagged-price variable reflects the normal "cobweb" relationship among consumption, production, and price. The price

Table 2. Rice production elasticities from structural equations[a] (at 1966 observations for nonlogs)

Nation	Elasticity definition					
	Q.A	Q.F	Q.P	(Q/A).F	F.P	A.P
Japan	0	.435	1.35*	.207	.440(−1)	
United States	1.06	.443	0(−1)	.089	−.056(−1)	0
India	3.19	.213			1.23	
Pakistan		.220(−1)		.207		
Indonesia	1.05			.007		
	0.20	.007	.061*(−1)	.016		.035(−1)
Thailand	.402		.318*	1.96		
Burma	1.04	.187	.035(−1)	.550	.150(−1)	0(−1)
South Korea	.853		.542*(−1)	1.97	.334	
Philippines			.086*(−1)			
	.169	.203	.371(−1)	.026	.113(−1)	0(−1)
Malaysia	.200	.374	0(−1)		0(−1)	
Brazil	1.06	.500	0*(−1)			
World	.93	.282			.179**(−1)	

[a] The coefficients of lagged independent variables are denoted by (−1) following the coefficient. All estimates are based on equations having statistically insignificant multicollinearity. Zero elasticity estimates are given only when the equation meets rigorous statistical tests and additional information supports this inelasticity presumption. The first letter in each case represents the dependent variable and the second the independent variable. "Q.A" is, for instance, response of output to changes in area (hectares harvested). The year 1966 was chosen as most representative for forecasting through 1975.

* Indicates that price is in real terms.

** The world price equals the unitary value of world rice exports.

Table 3. Rice price elasticities, simultaneous estimates[a] (at 1966 observations for nonlogs

Nation	P.(GNP/POP)	P.GNP	P.A	P.F	P.P (−1)
Japan	.964		.0000039	−3.92	
United States	1.45		−1.78	−.745	−.111
India	11.46		−30.19	−1.81	−.102
Thailand	.110		.110		
Burma[b]		−.787	2.96(−1)	−.421(−1)	.003

Philippines	9.34		−.433	−.520	−.953
Malaysia	1.42		−.220	−.410	−.010
Brazil	31.27		−13.42	−6.33	.139
World	2.15		−1.00[c]	−.230	−.040

[a] All elasticities are derived from solving at least two equations simultaneously (at least one demand and one supply). Where the price coefficient was insignificant but of positive sign, we assumed its actual sign was negative in order to retain the appropriate signs for various elasticities. These are shift elasticities that indicate the responsiveness of equilibrium prices to independent variable changes. Three nations are excluded: Complete estimates were not available for Pakistan; we have no consumption equation for Indonesia; West German production is so small that no output estimates were made.
[b] Nominal price is substituted for real price.
[c] No direct estimates of the aggregate responsiveness among area, output, and price was made. This estimate is based on major-producing-nations results.

changes forecasted from changes in per capita income, area utilized, and fertilizer demand will themselves have an impact on production.

In general, those nations having either price supports or price ceilings can be identified by the sign of the estimated net annual change in price. There are, for instance, price ceilings in South Korea and in Brazil where price changes are estimated as positive. All the "free market" price-change estimates (Table 4) suggest only what price changes *would be* if no nations adopted the new varieties. Not all of these estimates are viewed with the same confidence.[7]

The introduction of the new miracle grains increases output substantially. We know that, other things being equal, such output increases would reduce rice prices in the particular country. Of the current miracle-grain adopters, a complete set of elasticity estimates for post-miracle-grains free market estimates of price changes through 1975 could be generated only for India, the Philippines, Brazil, and from the world equations (Table 5). Because of the difficulty of shifting resources into alternative employment in less developed nations, we assume that in fact there would be a downward stickiness in output changes in response to price declines. The positive responses to upward price movements have been supported by government assistance and persuasion in most LDC cases. For simplicity we assumed throughout that the responsiveness on the downside would be only half as great as on the upside of price changes (the semiresponsiveness category). Except for this qualification, these estimates are derived in the same way as those in Table 4.

[7] In the Burmese equations income and area are highly correlated. The effect on prices of changes in fertilizer inputs is probably accurate. But the impact of changes in area planted is of the wrong sign. This effect is probably counterbalanced by the very small indicated impact of the lagged price. In short, while the price change attributed to area is probably incorrect, the net annual change may be very close to the true figure.

Table 4. "Free market" estimates of price changes (without miracle grain impact), 1967–1975[a]

	Japan	United States	India	Thailand	South Korea	Burma[c]	Philippines	Malaysia	Brazil	World
Average annual price change percentage attributed to changes in:

[a] Forecasted annual changes in the independent variables appear in brackets. Where experts disagree with these forecasts, the price changes can be easily recalculated.
[b] Negligible.
[c] GNP substituted for per capita income.

Table 5. Postmiracle-grain "free market" estimates of price changes, 1967–1975[a]

	India		Philippines		Brazil		World	
	Symmetrical	Semi-responsive	Symmetrical	Semi-responsive	Symmetrical	Semi-responsive	Symmetrical	Semi-responsive
Average annual price change percentage attributed to changes in:								
Per capita income	22.23	22.23	13.64	13.64	56.29	56.29	4.79	4.79
Area	−39.85	−78.49	−.344	−.688	−7.88	−15.76	−1.50	−3.00
Fertilizer	−18.62	−37.23	−23.71	−47.54	−39.55	−63.30	−5.31	−9.64
Lagged price	3.70	4.67	9.92	16.46	1.23	−1.59	−0.08	.107
Net annual change (percent)	−32.54	−88.82	−1.18	−18.13	+10.09	−24.36	−2.10	−7.74

[a] New marginal physical products relating fertilizer inputs to output were calculated from nonstatistical postmiracle-grain output estimates and least-squares estimates of fertilizer demand. "Symmetrical responsiveness" assumes that output response to price declines is identical to that for price rises. "Semiresponsiveness" assumes downward output stickiness and that production is only about half as responsive to price declines as to price rises.

Impact of price changes on rice output

Output changes in response to rice price changes (as percentage deviations from the constant-price forecast) can be estimated from the simultaneous price adjustments and from the input elasticities of the structural equations by multiplying estimated net annual price changes by the price elasticity of fertilizer and that by the fertilizer elasticity of output, that is, $\%\Delta\hat{Q} = \%\Delta(\hat{P}/C\hat{L}I) \cdot (F.P) \cdot (Q.F)$. Where estimated elasticities are very large, we have a special statistical problem. All of the estimated price elasticities from the original structural equations are of course increasingly inaccurate as we move from the mean values in these relations. An equilibrium shift that results in a 20 percent price decline, for example, would move the supply curve to an intersection of the demand curve that is a great distance from the estimated mean of the quantities demanded. It is virtually certain that the coefficients of elasticity at the new point on the demand curve are substantially different from these estimated values. To adjust for this, we assume that the impact of all "extreme" price changes are exhausted in a limited number of years. In terms of output changes, this turned out to be a problem only for India and South Korea.

In virtually all nations the constant-price *consumption* figures do not deviate from the consumption estimate at alternative prices. A significant price elasticity coefficient for the *nominal* world price was derived, however, and was used in estimating an adjusted world consumption total. The consequences of adjusting production and consumption estimates for price-change impact are reflected in the trade estimates at changing prices (Table 6).

World and National Production, Consumption, and Trade Estimates, 1967–1975

Total 1975 world consumption and production estimates[8] appear in Tables 7 and 8. We expect that the increased volume of rice moving in world trade (about 10 percent of total Q_r by 1975) will result in a higher average price elasticity than now prevails because rice will increasingly become a private market commodity. If world rice prices remain at their 1966 level through 1975, the total world production surplus is estimated at an annual rate of 26.56 million milled metric tons. In reality, of course,

[8] Total world and national rice production and consumption equation estimates yearly, 1967–1975, are available upon request.

Table 6. Rice trade of selected major nations at changing "free market" prices, 1975 (in millions of milled metric tons)

Nation	At premiracle-grain price changes	At postmiracle-grain price changes	
		Symmetrical	Semi-responsive
Japan	−.099[a]	—	—
United States	1.960	—	—
India	−6.560	−8.580	−3.780
Thailand	3.582	—	—
Burma	1.923	—	—
South Korea[b]	8.285	—	—
Malaysia	−.342	−.342	−.342
Philippines	.531	.331	.471
Brazil	.838	.838	.838

[a] A negative sign indicates that the nation is a net importer.
[b] There apparently are severe structural problems in South Korea unrelated to producer responsiveness that would prevent this high export figure from being attained.

the miracle grain revolution will have an impact on rice-price changes. After all producers and consumers have adjusted as expected to price changes through 1975, we expect a world surplus in rice equaling 8.74 million milled metric tons at an annual rate. The nominal world price of rice will have declined by 62 percent from its 1967 figure level by 1975.[9] The final consumption adjustment would narrow the surplus to only 2.34 million metric tons.[10] What follows is some country-by-country results.

The "most likely" national trade balance figures appear in Table 9 below, except for Indonesia, Nepal, South Vietnam, and Mainland China estimates. On the basis of FAO estimates of 1975 consumption, Indonesia is expected to import a net 2.95 million milled metric tons in 1975 at constant prices. This trade deficit would probably move close to zero if miracle grains are adopted successfully. The FAO estimate of consumption for Nepal indicates that the country will continue to run a trade surplus of an estimated 800,000 in 1975. With continued adoption of the IRRI varieties and a substantial diminution in the war by 1972, self-sufficiency by South Vietnam should be obtainable again. According to the FAO estimate of 1975 consumption, South Vietnam should be exporting an estimated 550,000 milled metric tons in 1975 at 1966 prices. Production and consumption forecasts from FAO for Mainland China include net exports of at least 650,000 milled metric tons in 1975.

The domestic farm rice price is supported by the governments of Japan, the Philippines, the United States, India, and Malaysia. The removal of such supports under the pressure of rising subsidy costs would result in the deflations estimated in Table 4. Presumably rice production in each of these nations would be lower also. In 1965 Japan's support price was more than 2.5 times the world average export price.

In all nations studied except perhaps Burma and Malaysia, most output increases are expected to come from more intensive cultivation and rising yields. In Burma and Malaysia area utilized for rice production has increased faster than in other parts of Asia. The miracle rice is expected to affect significantly production in India, Pakistan, the Philippines, and South Vietnam; for these nations we need initially

[9] To illustrate how surpluses could be influenced by the failure to take into account possible interdependencies between production and demand, we adjusted these price-influenced totals (World surplus I in Table 7) by an *arbitrary* 3 percent extra increment of consumption (World surplus II).

[10] In terms of strict statistical interpretation, these estimates are midpoints within a range of possible values.

Table 7. Total rice production at changing "free market" prices, 1975 (in millions of milled metric tons)

Nation	At 1966 prices	With non-miracle, symmetrical price changes	With miracle price changes: Symmetrical	With miracle price changes: Semi-response
Japan	14.43	12.70	—	—
United States	3.18	3.20	—	—
India	49.27	38.60	36.58	41.38
Pakistan	17.02	—	—	—
Thailand	10.97	11.16	—	—
Indonesia	9.12	—	—	—
Burma	6.41	6.42	—	—
South Korea	4.65	12.37	—	—
Nepal	2.11	—	—	—
Malaysia	1.16	—	—	—
Philippines	6.80	6.80	6.60	6.74
South Vietnam	4.78	—	—	—
Brazil	7.69	7.69	7.69	7.69
Mainland China (FAO)	72.70	—	—	—
Rest of World	13.50	—	—	—
World production totals	223.79	225.42	220.93	222.07
World consumption totals	197.23	192.07	201.60	213.23
World surplus I	26.56	33.35	19.33	8.74
World surplus II[a]	20.64	27.59	13.28	2.34

[a] This estimate is derived by increasing total consumption an arbitrary 3 percent because of supply-demand interaction.

Table 8. Total world rice demand at 1966 prices, 1975

Japan	12.80
United States	1.24
India	45.16
India (adjusted)	(47.87)
Pakistan	14.19
Thailand	7.58
Burma	4.50
South Korea	4.09
Philippines	6.27
Malaysia	1.51
Brazil	6.85
West Germany	0.24
Rest of world[a]	92.80
World total	197.23

[a] The value for "rest of world" is derived from an aggregate world equation. Of the "rest of the world," about 79 percent is attributable to Mainland China and another 14 percent to Indonesia. It was not possible to obtain accurate data for Mainland China and usable income statistics were not available for Indonesia (or Vietnam).

Table 9. Rice trade of major nations at 1966 prices, 1967–1975 (in millions of milled metric tons)

Year \ Nation	Japan	United States	India	Pakistan	Thailand	Burma	South Korea	Malaysia	Philippines	Brazil

1973	1.501	1.810	3.596 [−2.634]	4.063 [1.657]	3.344	1.774	.443	−.316	1.978 [−1.786]	.404
1974	1.571	1.875	3.564 [−2.361]	4.120 [1.830]	3.369	1.842	.503	−.329	1.320 [−2.399]	.616
1975	1.631	1.940	1.400 [−2.107]	3.826 [1.946]	3.392	1.913	.565	−.342	.531 [−3.144]	.838

[a] The trade values in brackets are based on least-squares equations estimates and hence do not include the effect of technological change. The difference in the two estimates indicate the impact of technological change (new seed varieties) on trade. A negative sign indicates that the nation is a net importer.

nonequation estimates of output.

There are only two exceptions to an estimated zero price elasticity of demand: Demand is estimated as sensitive (in the normal direction) in Malaysia; rice appears to be a Giffen-good in Burma.

Except for the above and subsequent qualifications, the reader can rely upon the tables for estimates. Contrary to the perverse response suggested by our statistically estimated output changes, a "free market" and U.S. rice price decline of 2.33 percent annually through 1975 would probably yield a somewhat lower level of production. As acreage controls and price supports have been such major factors in the American market, we have been unable to estimate accurately the responsiveness of American producers to such price declines. The responsiveness of output to both fertilizer and irrigation inputs could rise substantially in Indonesia. Because of problems including those with land tenure, production credit, effective water control, and continued expansion of cultivated land, we have discounted a similar possibility in Thailand.

Although statistically South Korean production *appears* to be highly sensitive to input changes, there seem to be substantial production-inhibiting forces in that country. The main constraint appears to be limited land availability, as we forecast a total increase in land utilized of less than 1/2 of 1 percent between 1970 and 1975. The apparent *lack* of statistical responsiveness of production to price changes in Malaysia is probably due to the fact that we were able to use only the export price in our equations for Malaysia rather than a domestic price. Elimination of the subsidy program there would result in an estimated annual decline in the real price of rice of 1.41 percent per year through 1975; *irrespective of our statistical results on responsiveness*, such price declines probably would reduce production.

Summary and Conclusions

In evaluating estimates of rice production, consumption, trade, and price changes, one should remember that the world has in the past decade produced enough rice to meet world demand. Starvation and low nutrition levels of people in less developed nations has resulted not from an inadequacy of world output capacity, but rather from unequal distribution of food output. If the green revolution is viewed with that perspective, it is clear that its first goal is the feeding of indigenous populations.

Traditionally the major Far East exporters of rice have been Burma, Cambodia, Taiwan, Thailand, and Vietnam. Other traditional ex-

porters include the United States, Mainland China, the United Arab Republic, and Brazil. The traditional Far East importers have included Japan, Ceylon, India, Indonesia, Malaysia, Pakistan, the Philippines, and South Korea. At constant prices many of these traditional Far East importers—India, Pakistan, the Philippines, and South Korea—are expected to be net exporters themselves during the 1970's. Only India and Pakistan would be exceptions to this shift if the domestic producer price of rice in these countries is allowed to decline sharply.

Moreover, Indonesia and Malaysia are attempting to move to a surplus position or at least reduce their imports and may adopt the miracle grains. The Soviet Union, recently a modest importer, has been aiming at self-sufficiency. If *current government policies* continue, the Japanese and American rice surpluses are expected to grow substantially through the 1970's. Although Thailand's trade surplus is expected to grow slowly, we expect substantial increases in the size of Burma's surplus. South Vietnam is expected to return to her traditional role as a rice exporter in 1972. The most conservative projection of the change in trading relations indicates that the green revolution will turn traditional trading patterns virtually upside down.

Several policy implications emerge from these expected new trade patterns. The United States Government may want to plan early a severe acreage restriction program. But even if the United States and Japan were to shift to subsistence rice production, there would still be a substantial world surplus of rice at constant prices (and hence downward price pressure) in 1975.

The main problems between today and 1975 probably relate to income distribution and levels. Because the new varieties of food crops require substantial supplies of fertilizers with irrigation and modern cultivation methods, this agricultural technology has largely benefited the larger, more wealthy farmers. There is a possibility that small farmers may gradually be pushed out of the market by the large producers, and tenant farmers may be evicted in certain nations. The sharecropping peasants live at or below subsistence level, owning only a few crude farm tools; the benefits of the green revolution may never reach them.

A second income problem is one of income maintenance in a world of declining rice prices. The governments in the LDC's will have to decide whether to control production increases (by acreage, storage, or both) or to subsidize rice production at increasingly higher levels. *The problem of declining prices is related to the problem of income distribution.* When rice prices fall they will reach that point at which production of local varieties will be unprofitable much sooner than they reach a point at which production of the miracle grain rice is unprofitable. Presumably, then, it will be the smaller farmers who will be most adversely affected by falling rice prices. The precise marginal income distribution from the revolution will of course vary by nation. Income levels in the traditional exporting LDC's also will be adversely affected prior to the new miracle grain users; these nations would include Burma, Thailand, and Indonesia.

Unless substantial governmental policy changes are implemented by both the developed and the developing nations, there will be a new major source of conflict between the rich and poor countries. LDC trade gains from this production breakthrough will not be forthcoming without the cooperation of the developed nations and rational production controls by the LDC's. The foremost advantages of the agricultural revolution are the possibilities of eliminating hunger and starvation while reducing LDC import needs and perhaps generating an environment in which population growth will be slowed. To achieve these gains, however, requires a relatively even distribution of marginal income. Unless the peasant populations are induced to participate in the miracle grain revolution, widening disparities in income distribution may still leave large numbers deprived of food supplies. Then the maldistribution of grains that was once global will be national as well.

Discussion: VERNON W. RUTTAN, *University of Minnesota*

I like the paper by I. J. Singh. I admire the skill with which he has successfully integrated recent extensions of the neoclassical theory of the firm (a) to incorporate the production, consumption, and investment behavior of the household-firm; and (b) in econometric method, recursive linear programming, and activity analysis to simulate the behavior of the agricultural sector of the Punjab during a period when the region was undergoing rapid change in agricultural technology and rapid transition from subsistence to commercial agricultural production. Singh has neglected, however, to tell us how closely his model projections synthesize actual behavior during the 1952–1968 period. I would like to see the results of model predictions based on alternative factor-factor and factor-product prices ratios. I would also like to see the implications of alternative and institutional arrangements in the labor, capital, and land markets explored more thoroughly.

I also like the paper by Howard Barnum. The paper skillfully analyzes (a) the impact of PL 480 grain shipments on total foodgrain production, commercial imports, and consumption and (b) the effects of a program of managing feedgrain stocks to reduce dependence of imports on total production, imports, and consumption. The first part of the paper is less impressive than the second part. The evaluation of the effect of introducing stochastic terms into the simulation seems to me rather trivial. I am troubled by his failure to relate his results to those of previous investigations, particularly the work of J. S. Mann. The stock management analysis is, in my judgment the most significant aspect of the paper. It is a real advance over the Raj Krishna paper.

My reactions to the paper by Canterbery and Bickel are somewhat different. I like the topic; I like the conclusions; but I don't care for the analysis. I find my esthetic sensibilities offended by the "adhockery" of their methodology.

My skepticism is greatest with respect to the production relations. The authors indicate that area, fertilizer consumption, and prices "explain" most of the changes in output of grains in 1955–1966. The authors seem unaware of the very substantial supply response literature for rice (by Behrman, Hussain, Krishna, Mubyarto, Managahas, and others). A review of the individual country studies indicates that a need for considerably greater precision in the specification of the variables that influence output or the two major components into which output can be partitioned (area planted and yield). The area planted to rice, in particular, is quite responsive in many areas to the prices of the individual commodities that directly compete with rice for area.

Let me summarize. I remain highly skeptical of the model employed by Canterbery and Bickel and of the estimated relationships presented. The authors simply do not know enough about the world rice economy to be playing the world rice market outlook game.

Discussion: LOUIS M. GOREUX, *World Bank*

I shall restrict my comments to the papers presented by Singh and Barnum.

Singh's study appears very promising and I would be interested to see further research in two directions. The first relates to farmers' behavior; the second to the link between the area studied and the rest of the economy.

(1) Professor Singh stresses that his pro-

gramming model simulates closely the process of agricultural development in the area. This claim should be supported by a careful analysis of the discrepancy between the actual data and those generated by the model between 1952 and 1965. The sensitivity of these discrepancies to the choice of the behavioral constraints should be studied. Thus the importance of the flexibility and adoption constraints could be assessed.

(2) Maximizing the farmer's objective function, subject to behavioral constraints, may not lead to maximum social welfare for the country as a whole. For resources transferable between the area and the rest of the economy (such as tractors, fuel, capital, and labor), the opportunity cost to the country may differ from the market price paid by the farmer. Short of building an optimizing model for the economy as a whole, experimentation with parametric variations of the shadow prices of the central resources could be conducted. Thus, investments in the area could be larger (or smaller) than the savings made in this area, depending on whether the opportunity cost of capital is higher (or smaller) in this area than in the rest of the economy.

In his paper Barnum finds, as Mann [1] did, that PL 480 induced a decline in grain prices to domestic producers and, consequently, in domestic grain production. I agree with this finding. However, I question the validity of some of the estimates.

The model has been estimated from historical data with PL 480. To use the same model for assessing what would have occurred without PL 480 one needs to be sure that suppressing PL 480 imports would not have affected some of the variables taken as exogenous.

(1) If the government had followed a sensible storage policy, the value of the yearly changes in government stocks should have been different without PL 480 imports. This is not taken into account.

(2) The suppression of PL 480 would presumably have reduced the capacity to import goods other than grains and consequently the value added by the nongrain sectors. Because this effect is not taken into account, suppressing PL 480 by raising domestic grain production automatically raises national product.

(3) If grain prices are positively correlated with the price of substitutes, reducing consumption should raise the price of the substitutes, provided that the supply elasticity of these substitutes is less than infinitely price elastic. Since the price of substitutes is assumed to remain the same with and without PL 480, reducing grain consumption by 10 percent induces only a 12 percent increase in the price of grains, which implies a price elasticity of $-.85$. The price elasticity of $-.34$ found by Mann and the NCAER seems much more reasonable.

(4) My main objection is to assume that with and without PL 480 the volume of commercial imports would remain a constant proportion (.1287) of grain availabilities before commercial imports (equation 3). PL 480 imports has accounted in some years for a large proportion of grain supplies in cities such as Bombay and Calcutta. Having suppressed PL 480 imports and increased commercial imports by only 13 percent of the PL 480 imports foregone would have caused a drastic reduction of grain supply in these cities. The true dollar cost of PL 480 imports was more than 15 percent of the cost of commercial imports. Why should the government have saved on the dollar cost of all grain imports if PL 480 had been suppressed? Experience in Mainland China suggests that to face a severe grain shortage in cities governments are ready even to reduce the import of capital goods.

I believe that improving the specifications of the model would probably be more important than introducing stochastic elements. We need to recall that we have a model only for the grain sector and that it is difficult to reconstruct what would have occurred in the absence of PL 480 without considering the trade-offs between the grain sector and the rest of the economy.

To conclude, I wish to stress that the production function estimated by Barnum is a very substantial improvement over the one estimated previously by Mann, especially regarding its dynamics properties.

Discussion: JOHN W. MELLOR, *Cornell University*

Until recently backwardness in agriculture was viewed largely as a product of cultural patterns inappropriate to quantitative economic analysis. Unfortunately, our conceptualization continues to suffer from failure to recognize the substantial extent to which common rules of thumb and observed relationships are the products of their environment and therefore potentially misleading in the different economic environment of early stage development [3, 5]. Weakness in conceptualization not only leads to erroneous intuition concerning policy but to erroneous specification of models and weak ability to note inconsistency and error in results. Models continue to suffer from paucity of analysis concerning assumed exogenously determined variables. More basically, a high proportion of current work assumes continuation of structural relationships which are themselves the antithesis of development.

Particularly useful in Singh's analysis is the effect of technological change on volume of marketings, a subject bound to revive in importance as the employment implications of the green revolution become more clearly related to transfer of agricultural commodities to the urban labor force [5]. The model poses a number of difficulties. Markets for labor, capital, and even land work surprisingly well in most low income countries; hence the rigid resource restraints so common in linear programming models are inappropriate [3]. Singh has been ingenious and successful in his specification of restraints. However, the flexibility restraints, such as rate of adoption of technology, are important to answering questions of timing but are so poorly understood that they remain important subjects of further research.

Barnum tackles smaller questions and is able to use more fully substantiated assumptions. Simulation of the market for foodgrains in India concludes that a decrease in domestic foodgrains production incident to PL 480 has been small. This is consistent with an earlier simulation of price effects [4]. The model illustrates dangers of use of past relationships to prescribe future policy. In India PL 480 foodgrains probably have not been used to expand employment. If they were, average demand elasticities would be reduced, prices would fall less or rise more than indicated, and the reduction in domestic production would be less than indicated. Simulation can be used to test the effect of such structural changes.

The Canterbery-Bickel paper illustrates the extreme problem of dealing with complex processes with current quantitative tools and data. Such a large number of arbitrary assumptions must be made that we are probably better off at the mercy of intuitive insights of experienced policy practitioners. Estimation of effects of a major new technology on trade patterns requires estimates of the production effects of the new technology where it is applied, the rate and extent of application, and the effect of the new technologies on income distribution and hence on the structure of demand. This latter problem is important, generally neglected, and probably causes substantial underestimation of the demand elasticities.

POSITION AND PROSPECTS OF BLACKS IN THE NATIONAL ECONOMY

(Joint Session, AAEA and AEA)

CHAIRMAN: JAMES G. MADDOX, North Carolina State University

Prospects for Black Farmers in the Years Ahead

HENRY PONDER

BLACK RURAL population is about three-tenths of the total black population. Most blacks and other minority groups, except the American Indians, live in urban areas. Between 1960 and 1968, about 28 percent of the drop in farm population was the result of the exodus of blacks and other minority groups [3, p. 58]. Many of the problems that beset blacks everywhere occur in their most severe, undiluted, and least hopeful settings in the countryside; and to the extent that rural areas continue to be a seedbed for the cities, the problems of the rural minority continue to be the problems of all [1, p. 161].

In 1964 there were 199,952 nonwhite farm operators in the United States [4, p. 760]. Of this total 92 percent were blacks and 8 percent were classified as other nonwhite. Ninety-two percent of all nonwhite operators were in the South, and of these 98 percent were black.

For this analysis black is used synonymously with Negro and nonwhite. The census data for nonwhites are treated as all black, since 92 percent and 98 percent for the United States and the South, respectively, are black. Even with this overstatement of the data for blacks, the conclusions should be valid.

Number of Farm Operators

The peak year for black farm operators was 1920, when they numbered 925,710 (Table 1). This was 14.34 percent of the total farm operators in the United States in 1920 (Table 1). In 1964 the number of black operators had decreased 80.1 percent from 1920. In 1964 one in each 19 farmers was black, compared to 1920 when one in seven U. S. farmers was black.

Since 1900 the South has been home for more more than 98 percent of all U. S. black farm operators, while the North had somewhat more than one percent and the West never reached one percent (Table 1). This distribution has great significance when one considers the history of race relations in this country.

The states with more than 10,000 black farm operators in 1964 were Tennessee (10,624); Georgia (11,233); Texas (11,489); Virginia (11,583); Louisiana (12,272); South Carolina (19,582); Alabama (20,936); North Carolina (27,442); and Mississippi (37,543).

Outside the South the states with the largest number of black farm operators were Ohio (496); Michigan (488); California (337); and Illinois (277). The number of black farm operators has been decreasing since 1900.

Tenure and Acreage

The black colleges and extension workers did a fairly decent job of instilling in black farmers pride of ownership. Since 1930 there has been a steady increase in the percentage of owners among black operators (Table 2). In 1964, 39.3 percent of all black farm operators were owners (Table 2).

The percent of part owners has also been increasing—from 4.8 percent of all black operators in 1930 to 17.4 percent in 1964 (Table 2). Part ownership gives the operator more flexibility in using his capital.

The number of acres operated by black part owners exceeded that of black full owners in 1964 (Table 3).

In 1964 black full and part owners made up more than 56 percent of all black farm operators. These two tenure classes farmed more than 10.2 million acres.

Blacks have not been involved in large numbers as farm managers. This is due to many things, but education is of prime importance. More than 80 percent of all black farm operators had eight years of education or less in 1964 (Table 4).

In 1964 the number of black tenants dropped below the combined total of owners, part owners, and managers for the first time (Table 2). The number of acres operated by black tenants

HENRY PONDER *is vice-president for academic affairs at Alabama Agricultural and Mechanical University.*

Table 4. Highest grade of school completed and percent of farms operated by nonwhite operators, the South, 1964

Highest grade of school completed by farm operators	Total number of farms	Percent of all farms
Elementary:		
0 to 4 years	67,779	36.72
5 to 7 years	62,707	33.97
8 years	20,158	10.92
High school:		
1 to 3 years	20,065	10.87
4 years	7,333	3.97
College:		
1 to 3 years	2,079	1.13
4 years or more	2,609	1.41
Total number of farms	184,578	100.00

has been constantly decreasing since 1920, from over 27.7 million acres in 1920 to just under 4.0 million acres in 1964 (Table 3).

Farms Operated by Nonwhite Operators in the South

The 1964 U.S. Census of Agriculture reports characteristics of farms operated by nonwhite operators for the South only. These statistics should be reliable, since the South had 92 percent of all nonwhite farm operators and of these 98 percent were blacks.

Value of farm

More than 69 percent of the farms operated by nonwhites in the South were valued at less than $10,000 in 1964 (Table 5). Nonwhite operators had 41 farms valued at $500,000 or more in 1964.

Size of farm

The average acres per farm operated by nonwhites was just under 45 acres in 1920 and just over 56 acres in 1964 (Table 5). The land in farms was just over 10.4 million acres in 1964 (Table 5).

More than 66 percent of all farms operated by nonwhite operators in the South were less than 50 acres in size in 1964; and fewer than one percent were 500 acres or more in size (Table 6).

Farms smaller than 50 acres operated by nonwhite operators accounted for 42 percent of the cropland harvested on all farms of nonwhite operators, but they accounted for 64 percent of the tobacco acreage harvested and 54 percent of the cotton acreage harvested on all farms operated by nonwhite operators [4, p. 762].

Table 5. Farms, acreage, and value of farms operated by nonwhite operators and percent of total for the South, 1964

Acreage and value of farms	Total number of farms	Percent of all farms
Number of farms	184,578	100.0
Land in farms (acres)	10,439,934	100.0
Average size of farms (acres)	56.6	
Value of land and buildings		
Average per farm (dollars)	10,064	
Average per acre (dollars)	176.48	
Value of farms (dollars)		
Less than 10,000	128,029	69.36
10,000 to 19,999	31,476	17.05
20,000 to 39,999	16,324	8.84
40,000 to 69,999	4,825	2.61
70,000 to 99,999	1,192	0.65
100,000 to 149,999	471	0.26
150,000 to 199,999	189	0.10
200,000 to 499,999	183	0.10
500,000 or more	41	0.02

Economic class of farm

The Bureau of the census defines commercial farms as farms with a value of farm products sold of $2,500 or more and those with less than $2,500 in sales provided that the operator was under 65 years of age and worked fewer than 100 days off his farm during the year.

Almost 64 percent of all farms operated by nonwhite operators in the South were classified as commercial in 1964. Approximately 70 percent of the farms of less than 50 acres operated

Table 6. Farms by size of farms operated by nonwhite operators and percent of total for the South, 1964

Size of farms (acres)	Total number of farms	Percent of all farms
Total number of farms	184,578	100.0
Less than 10 acres	25,613	13.88
10 to 49	97,681	52.92
50 to 69	17,308	9.38
70 to 99	16,769	9.09
100 to 139	11,529	6.25
140 to 179	6,257	3.39
180 to 219	3,244	1.76
220 to 259	1,863	1.01

1,000 to 1,999	163	0.09
2,000 or more	57	0.03

Table 7. Amount of income of all household members and percent of total farms operated by nonwhite operators, the South, 1964

Income of households	Total number of farms	Percent of all farms
$1 to $499	35,388	19.17
$500 to $999	30,335	16.44
$1,000 to $1,499	18,606	10.08
$1,500 to $1,999	12,175	6.60
$2,000 to $2,999	15,760	8.54
$3,000 to $3,999	10,265	5.56
$4,000 to $4,999	5,919	3.21
$5,000 and over	9,039	4.90
Income of households from other sources greater than value of farm products sold	69,857	37.85
Total number of farms	184,578	100.00

by nonwhites sold less than $2,500 of farm products in 1964. Farms less than 50 acres in size accounted for 53 percent of the total value of farm products sold from farms operated by nonwhite operators [4, p. 762].

The Department of Agriculture figures as a rule of thumb that a farmer must sell at least $10,000 worth of products annually if he expects to make a minimum net income of $2,500 and that he needs $2,500 of net income to maintain a minimum decent level of living [1, p. 179]. In 1964, 75 percent of nonwhite operators of commercial farms sold less than $5,000 of farm products.

The average value per farm of all products sold was $2,705 for farms operated by nonwhite operators in the South in 1964. Slightly less than 40 percent of all nonwhite farm operators in the South reported income they and members of their households received from other sources to be greater than the value of farm products sold in 1964 (Table 7). Just under 20 percent of these had other incomes of less than $500.

Type of farming

In 1964 cotton and tobacco farms made up over 75 percent of all the commercial farms operated by nonwhite operators in the South (Table 8). These crops are labor intensive and make use of the operator's family labor. For the same period and group, 62 percent of the farm acreage was devoted to these crops.

Approximately 55 percent of the tobacco farms and 86 percent of the cotton farms had less than $5,000 of farm products sold in 1964.

Conclusions

It is a fact in history that blacks were imported to this country to help the agricultural economy of the South. The South is where slaves landed, and for the masses it is where they stayed. It is not surprising that in 1964 98 percent of all black farm operators were in the South. Whatever the black farmers' future, it is tied closely to the South.

Farming is a declining industry, and the number of black farm operators has shown a steady decline since 1920. The exodus of black farm operators is expected to continue to decrease in the future, but at a decreasing rate.

The decrease in black farm operators is reflected by decreases in all the tenant classes. A

Table 8. Characteristics of commercial farms operated by nonwhite operators, by type and percent of total for the South, 1964

Average size and value of farms	Total commercial farms	Tobacco	Cotton	Poultry	Dairy	Livestock farms except poultry and dairy	General
Farms—number	117,090	31,421	58,176	455	1,154	4,713	8,397

[a] Percentage does not add up to 100 because the following type farms are missing: cash-grain, other field-crops, vegetables, fruit and nuts, and miscellaneous.

good sign is that the percentage of owners and part owners is increasing for black farm operators and the percentage of tenants is decreasing.

The trend toward ownership of land has increased, while the number of acres owned by black farm operators has been decreasing. In the 10-year period 1954–1964 black land ownership decreased from 14.1 million acres to 10.2 million acres. The average acreage per farm for black owners was 65.2 acres in 1964.

Land ownership is of prime consideration to remaining in farming, because the tenant must give up his land when the owner wishes it. With mechanization increasing, more owners will be farming more land. This will cause a further decrease in the number of black farm operators.

Black operators had only an average of $176.48 invested per acre in 1964. More than two-thirds operated farms valued at $70,000 or less in 1964. Almost 70 percent farmed less than 50 acres. This is an indication of why three-fourths of these farms sold farm products worth less than $5,000. Since $10,000 in farm product sales is considered adequate, an overwhelmingly large number of black operators are in the poverty class.

Lack of education, along with other factors, indicates that the future role of the black operator will be that of a tenant or hired hand, if he remains in farming.

Three-fourths of commercial farms operated by black farmers were cotton and tobacco farms. Most cotton is farmed mechanically, and blacks have small farms that make this unprofitable.

Tobacco is labor intensive and is more suited to the small farms operated by blacks. The future will see more mechanization of tobacco farming, which will place the black operator at a disadvantage.

The above seems to indicate a dismal future for black farmers. When we add to the picture the culture and tradition of the rural South, the black farmer's future is dismal indeed.

If the black farmer needs credit to purchase a farm, he usually finds the lending agencies unresponsive to his requests. Even the federal lending agencies are generally not receptive to his request for a loan. This lack of receptiveness on the part of lending agencies is helping to decrease the number of black farm operators.

Black farmers have discovered that it is very difficult to become members of the various county and community agricultural committees. The Department of Agriculture's Agricultural Stabilization and Conservation Service plays a major role in the South's farm economy. ASCS county and community committees allot the acreages under the farm program for cotton, tobacco, and peanuts, the crops that occupy over 75 percent of black farmers. Yet in 1964 not one black was on a state ASCS committee and only a few were on the elected committees [5, p. 8]. This nonrepresentation is serving the purpose of driving blacks out of farming.

The same criticism may be made of the Extension Service. There are very few black Extension agents in the United States, but many do serve as assistants. Historically, Extension is the USDA education arm; it also represents a close alliance between the Department and the segregationist establishment in the South [2, p. 16]. Black Extension agents are needed to help black farmers secure loans and improve their farming methods.

The lure of improved civil rights in other sections of the United States has caused a large number of blacks to leave the farms of the South. This exodus cannot be stopped unless the treatment of blacks is improved.

The above indicates that the migration of black farmers to the urban centers wlll increase in the years ahead. The rate of migration may decrease, but the trend will remain. This trend will continue unless a concerted effort is made to stop it.

The problems of the black farm operator are grave. They merit the attention of the federal, state, and local governments as well as local citizens. Studies should be undertaken to determine what steps can and should be taken to keep black farm operators "down on the farm."

Rural-Urban Migration of Blacks: Past and Future*

CALVIN L. BEALE

AFTER THE 1920 population census Congress failed for the only time in its history to reapportion the seats of the House of Representatives. When the census results were in, it was found that for the first time urban population exceeded rural in the United States. Representatives from rural states that stood to lose a seat in reapportionment argued either for an increase in the size of the House to protect their absolute representation or favored no reapportionment at all. The affected states were in the Midwest, New England, and the South. Thus the issue was by no means a narrowly sectional one. But one major contributing factor was the migration of rural southern Negroes to northern industrial states, which the southern congressmen insisted was only temporary.

"For the last two years," said Representative Johnson of Mississippi, "there have been special trains carrying thousands of Negroes and a great many white people to the northern cities, and since this financial condition has come about in the country [i.e., the postwar economic recession] hundreds and thousands of these same people are trying to return to the South" [2, p. 1633]. "Thousands of (Mississippi's) citizens were temporarily employed in other sections of the country and they were not enumerated. Thousands of her citizens, mostly colored, were temporarily removed to Chicago and other places before the recent election, to be used politically. They have been used and are now returning to their homes, poorer but wiser" [2, p. 1645]. Representative Bee of Texas gave the ultimate assurance to the House: "Just as certain as God reigns [the men who have gone to the cities] must go back to the farms" [2, p. 1633]. Rural partisans at times frankly admitted their objection to a reapportionment that would "take away the strength and the power and the control of the Government from the rural districts and center it in the congested districts" [2, p. 1634].

In the end Congress was not able to agree on any new plan, and the 1910 census continued to be used for apportionment until the election of 1932 [4, pp. 120–122]. I recount this now nearly forgotten incident in our history to remind us that rural-urban migration of blacks (or whites) is not just a recent phenomenon or one that has only in our day affected public policy. Needless to say, comparatively few of the World War I migrants ever returned to the farm for very long. Nor did the outmovement cease with the end of the war. All but one of the states that would have lost House seats in a 1920 reapportionment proceeded to lose when the 1930 census was taken.

Although the farm population began to decline during World War I, the total white rural population continued to increase until 1940 as gains in the nonagricultural rural sectors more than offset losses from farms. The Negro rural population, however, was more highly concentrated in agriculture and 97 percent of it was in the South. When the black migration away from southern farms began, as a result of the new opportunities in the industrial North, the ravages of the cotton boll weevil, and the inability of eroded areas in the older plantation belt to produce cotton profitably, a decline in the total rural black population took place that has never been reversed. This population fell in fairly similar decade amounts from 7.1 million in 1910 to 6.6 million in 1940. There are no data on the actual number of black rural-urban migrants, but a defensible estimate would be a net of about 2.5 million during this 30-year period. The decline would have been heavier had not the rise in the popularity of cigarettes brought in tobacco as an alternative to cotton for many Negro farmers in the South Atlantic states and had not the Great Depression retarded rural-urban movement in general.

With the coming of World War II, the pace of migration to the cities changed drastically for whites and blacks alike. Burgeoning defense industries provided unprecedented job opportunities; compulsory military service took many of the young men away; and in the Delta the first large-scale displacements of tenant farmers through mechanization occurred. There was a

*The author is grateful to Gladys K. Bowles and Vera J. Banks for their assistance with the data from the Survey of Economic Opportunity used in this paper. These data were obtained from a cooperative study on the Poverty Dimensions of Rural-to-Urban Migration, conducted by the Economic Research Service, USDA, and the Institute for Behavioral Research, University of Georgia, and funded by the Office of Economic Opportunity.

CALVIN L. BEALE is *leader of the population studies group, Economic Research Service, USDA.*

brief period of return movement to farms in 1945–1946 after the end of the war. However, this was just a momentary interruption in a sustained flow of people to the cities that has persisted to the present.

The majority of black farmers were cotton tenants. As the market for cotton fell and harvest mechanization came in, they were in a particularly vulnerable position. Those who were tenants had no control over their own future in farming, and mechanization—soon augmented by chemical weed control—eliminated about 10 tenants for every 3 regular hired hands that it added. Black farm owners typically had farms that were far too small to yield a minimally adequate income (84 percent of them grossed less than $2,500 in 1959). Their average age was high, for nearly all of their grown children had left, wanting nothing to do with the occupation that they associated with the poverty of their parents.[1]

In 1950 only one percent of the cotton grown in the South (excluding Texas and Oklahoma) was machine harvested. By 1959 the figure was 25 percent; by 1969, 94 percent. The need for cotton hand labor has almost vanished. Simultaneously, acreage cutbacks and labor-saving devices have reduced the number of black tenants in tobacco farming, and peanut production—the third most important type of farming for blacks—has been mechanized.

In sum, the last 20 years have seen the departure through displacement, voluntary withdrawal, or old age of the great majority of black farm operators. There were 560,000 of them in 1950. Today unpublished surveys by the Economic Research Service indicate that no more than 100,000 are left.

The principal role of Negroes in American agriculture has changed to that of hired farm worker. More than a half million blacks still do some hired farm work, and they perform about a fifth of all man-days of farm wage work done in this country. But a majority of these workers no longer live on farms.

From 1940 to 1960, I estimate net rural-to-urban migration of blacks was about 3 million. This left a rural black population of 5.1 million in 1960, compared with the 1910 maximum of 7.1 million. However, it is essential to note that all of the net rural decline was from the farm population. The rural-nonfarm black population increased in every decade from 1920 (when the farm-nonfarm identification was first made) to 1960, rising from 1.8 million to 2.7 million. In 1960 rural-nonfarm blacks exceeded those on farms for the first time. The steady growth of the nonfarm rural population suggests that in the future the overall rural black decline may end as further losses from the now much-depleted farm sector become too small to offset nonfarm growth.

Data from the 1970 census of population are not yet available by race and residence. We know, however, from our cooperative annual surveys with the Bureau of the Census that the decline in the Negro farm population has continued to be precipitous since 1960. This population has been reduced by more than half in just 10 years, and today numbers less than one million. It would be impossible for future outmigration of blacks from farms to be as large in the next decade as in that just past, for there would be none remaining in another six or seven years if the recent absolute losses were maintained. The recent loss from farms has been so large that I doubt that rural-nonfarm gains have yet fully offset it. Census returns from the 158 nonmetropolitan counties in the nation in which Negroes comprised a majority of the rural population in 1960 show a mean decline of 6 percent in the total population of these counties from 1960 to 1970.

What of the characteristics of the migrants who left the rural areas? The proportion of rural blacks who have gone to urban areas in the last generation is so high that it includes large numbers of all segments of the population. Based on our cooperative research with James Tarver for the 1950–1960 period, I estimate that the 25–29 year-old cohort of Negroes living in rural counties in 1960 represented little more than a third of the original group of that age who were born in those counties. It is the population remaining behind in the rural environment that is more likely to be of selective composition than that which has left.

Recently new information has become available on the cumulative extent of rural-urban migration and on characteristics of the migrants. This is the data file from the Survey of Economic Opportunity, collected for the Office of Economic Opportunity by the Bureau of the Census in February 1967. In this 30,000 household national sample, data were obtained on the previous residence history of the population and related to current residence and character-

[1] For a general discussion of the characteristics of Negro farmers and factors affecting their numbers, see [1].

Table 1. Selected characteristics of the adult Negro population, by migration status, February 1967[a]

Characteristic	Rural population of rural origin	Rural-urban migrants[b]	Urban population of urban origin
Population, 17 years plus (thousand)	2,389	2,056	7,040
Families (thousand)	836	874	2,649
Unrelated individuals (thousand)	194	329	863
High school graduates (percent)	15.9	25.9	38.7
Median years of school completed	8.0	8.8	10.9
Children ever born per 1,000 women, 35–44 years old	4,937	3,360	3,470
Median family income, 1966	$2,778	$5,116	$5,105
Population in poverty (percent)	57.7	26.6	26.9
Families receiving any public assistance income, 1966 (percent)	19.9	17.3	15.6

[a] Population 17 years old and over, by 1967 residence and residence at age 16 or earlier.
[b] Migrants are persons who have ever lived more than 50 miles from their 1967 address.
Source: 1967 Survey of Economic Opportunity.

istics.[3] Migration was defined as a move of at least 50 miles distance. Tabulations compare current residence with that at age 16. Using this definition of migration, which I regard as reasonably conservative, there were 9,096,000 urban blacks 17 years old and over in 1967, of whom 2,056,000, or 22.6 percent, were of rural migrant origin. This number of rural-urban migrants is much smaller than the sum of the decade numbers cited earlier, but it must be remembered that it relates only to persons still living, excludes children under 17, and treats as nonmigrants persons whose rural-urban move was less than 50 miles.

Of the rural-urban black migrants, three-fourths were living in the central cities of metropolitan areas. Only 12 percent had gone to nonmetropolitan urban places, compared with 25 percent of white rural-urban migrants.

Among urban blacks 50 years old and over, a third were of rural migrant origin. This proportion dropped to 14 percent at ages 17–29, where much of the potential movement had yet to take place. But in view of the large number of urban-born blacks at this age group, it is unlikely that the percentage of rural migrant people will ever be as large in this cohort in the future as it is among persons presently of middle or older age.

Fully half of the black rural-urban migration has involved an interregional move from the South to the North or West. In this characteristic the black rural-urban migrants were far different from the white migrants, only one-tenth of whom had moved interregionally from the South to the rest of the country.

Educationally the rural-urban black migrants were intermediate between city natives and rural residents; 26 percent of them were high school graduates, compared with 16 percent of the rural residents and 39 percent of the urban natives. Some of their educational disadvantage was the product of the older average age of the migrants. When the population was grouped into three age ranges—17–29; 30–49; 50 and over—the differential between rural-urban migrants and urban natives was found only above age 30. At ages 17–29 the median attainment of the two groups and the proportion completing high school were essentially identical. But this means that the differential between the rural-urban migrants and rural nonmigrants has widened. In past years so few rural Negroes had obtained high school training that there was no possibility for extensive outmigration without drawing heavily from the poorly educated. In more recent years improvements in rural education have produced more differentiation in that population in level of schooling, and the selectivity of outmigration by education seems to have increased. Among blacks of rural origin 17–29 years old in 1967, about one-half of those who were high school graduates had moved to cities, whereas only one-sixth of those who had 8 years or less of schooling had done so. In all age groups the higher the amount of schooling, the higher the proportion who had moved to the city. To a partial but unknown extent some of the higher education of the migrants results from education obtained after their move to the city. The intermediate level of education of rural-urban black migrants has served to lower the average level of education in both the black population of origin and the area of destination.

In economic activity black rural-urban migrant men compared as follows with their urban-reared neighbors: The migrants were just as likely to have had some employment in the preceding year. (No measure of current unemployment was taken). If employed, they

[3] See Table 1 for selected characteristics of the adult Negro population by migration status in 1967.

were somewhat more likely to have had full-time work (50–52 weeks) and less likely to have "white collar" jobs or to work in the industries in which such jobs are most common, such as trade, public administration, or professional services. Their most common work was as operatives in manufacturing industries.

Despite some overall disadvantage in education and job structure, black urban families headed by a migrant of rural origin did not experience lower average income than other black urban families. Their median (in 1966) was $5,116, compared with $5,105 for the families with urban native heads. A factor acting to produce this parity of income was the more normal composition of the rural migrant families. Seventy-four percent of them had a male head, compared with 69 percent male heads among the urban native families. Families headed by males had double the average income that families with female heads had. When families are considered separately by sex of head, the urban native families headed by men averaged about $300 more in median income than the comparable rural migrant families. A similar difference was indicated for families headed by women but was not statistically reliable.

Among persons living alone or with nonrelatives—the group called unrelated individuals in census data—the rural-urban migrant group averaged somewhat less income than urban natives. The income superiority of the urban natives among unrelated individuals held for both men and women.

When the income data were related to age and family size the following picture of the incidence of poverty appeared, using the standard federal poverty definitions. Of rural-urban black migrants 17 years old and over, 26.6 percent were in poverty, compared with 26.9 percent of the black urban population of urban origin. In other words, the incidence of income poverty among the two populations was almost identical. Black urban residents of rural origin are not more likely to be poor. This overall identity is *not* the chance product of any systematic pattern of internally higher poverty incidence among the migrants that is masked in the aggregate by structural differences in the two populations.

Needless to say, the black rural-urban migrants have a higher incidence of poverty than their white counterparts, of whom one-tenth were in poverty. But it is only among whites that rural-urban migrants show a consistently greater amount of poverty than urban natives. (The difference among whites is not a major one—10.1 percent against 7.4 percent—but is consistent when further classified by age, marital status, education, occupation, and other variables.)

Despite the fact that a fourth of rural-urban black migrants were in poverty in 1966 their migration seems to have been effective in greatly reducing the level of poverty over that prevailing in rural areas. Of the black population still in rural areas, 57.7 percent—more than double the urban proportion—were in poverty. The median income of rural black families ($2,778) was little more than half that of urban families of rural origin.

The Survey of Economic Opportunity also contains the first national information on receipt of money income from public welfare programs, by migration status. In February 1967 there were in the black urban population 151,000 families and 58,000 individuals of rural-urban migrant status who had received some income from public welfare sources in the preceding year. They accounted for 11 percent of all urban families receiving such assistance and 9 percent of the individuals who did so. Among blacks the rural-urban migrant family or individual was nominally slightly more likely than urban natives to have received welfare income assistance. Such income was received by 17.3 percent of the migrant families and 15.6 percent of the urban natives, and 17.6 percent of the unrelated individual migrants and 14.4 percent of the urban natives. However, these differences are not statistically significant from a sampling standpoint and, if real, would be rather minor in any meaningful effect on welfare programs.

The effective impact of black rural-urban migrants on urban welfare caseloads lies in the low average income levels and higher assistance needs of blacks in general and not in any differential propensity of migrants to need or obtain welfare money. Rural-urban black migrant families were somewhat less likely to have received welfare money than blacks still living in rural areas. In equity the frequency of welfare assistance should have been much greater for rural blacks than it was, in view of their very low average income. But in rural areas only 28 percent of the black families in poverty reported having any public welfare income. Black families of rural origin in the city were

less likely to need welfare assistance than their rural cousins but were more likely to get it when in poverty (42 percent) and received substantially higher average payments.

One major difference between rural-urban black migrants and the population that has remained in rural areas is the rate of childbearing. The number of children ever born per 1000 rural-urban migrant black women 35–44 years old was 3360. This is more than 30 percent lower than the childbearing rate of 4937 children per 1000 black women of the same age who still lived in rural areas. We cannot say how much of the difference is the result of selectivity of migrants at the time of move and how much results from lowered fertility after moving to the urban setting. In any case the lowered childbearing of rural-urban migrants is an important factor in their much lower rate of poverty compared with the rural population, for heavy child dependency is a major feature of Negro poverty. To my own surprise, the fertility of rural-urban black migrants proved to be no higher than that of urban natives (3470 per 1000). I do not believe we have previously been fully aware of the magnitude of fertility selection and/or reduction associated with black rural-urban movement.

A final point that I want to make in this discussion of the characteristics and fortunes of the migrants concerns differences in status by decade of migration. The incidence of poverty for rural-urban migrants who were 30–49 years old in 1967 has been tabulated by the decade in which they made their rural-urban move. Naturally those who had moved earlier would have had more years in which to adjust to the urban environment and advance their incomes. They would also tend to be somewhat older than the more recent migrants, within the age-span limits used. Among black migrants there was no consistent pattern or meaningful difference in the incidence of poverty among those who had moved before 1940, in the 1940's, in the 1950's, or after 1960. The poverty rate was 21.8 percent among those who moved in the 1960's and 18.6 percent among those who moved before 1940. In striking contrast, the incidence of poverty among white rural-urban migrants was strongly associated with decade of move. A phenomenally low 1.0 percent rate of poverty was found among whites who moved to the city before 1940. The rate rose progressively for those moving in succeeding decades to a high of 8.5 percent for the migrants who came in the 1960's.

The general picture that emerges from the Survey of Economic Opportunity material is that black rural-urban migrants, despite a distinct educational disadvantage until recent years, have succeeded in earning average family incomes nearly the equal of that of black urban natives and in doing so have avoided any incidence of poverty disproportionate to that of other urban blacks. Nor do they appear to have any but a marginally greater reliance on welfare income. I doubt that these findings conform to the general stereotype of the economic status of black rural migrants, especially those who have come to northern and western cities from the South. Furthermore, on any available scale of comparison their economic and educational status is far superior to that of blacks still living in rural areas. It is well to reiterate, however, that the black rural-urban migrants are far more afflicted with poverty in the cities than their white counterparts.

The impact of future rural-urban migration of blacks is conditioned by the fact that not more than one-fourth of the total black population (at most) now resides in rural areas, compared with better than one-half in 1940 when the large-scale movement began. The great majority of Negro youth are city-born today. In the future rural-urban migrants will not comprise as high a proportion of the urban population as they have in the recent past; nor will their absolute numbers be as large, for the rural base population is smaller, particularly the farm population from which so many people have come. In addition, nonfarm rural employment is supporting larger numbers of blacks than in the past.

On the other hand, these considerations do not imply that rural-urban outmigration of blacks is over. Several factors insure its continuance in the near future: (1) The fertility of the rural population is still very high in modern terms. The present Negro rural population bears enough children to more than double its size in every generation. This creates a potential labor force growth rate that in most areas far exceeds the capacity of the economy to match it with new jobs and thus leads to outmigration. (2) Negro rural youth have a positive preference to live in urban areas. A recent study of rural high school youth in three East Texas counties showed that 63 percent of

the Negro students wanted to live in a large city. The figure for white youth was only 16 percent [3]. A Florida study showed similar results [5]. The economic status and opportunities of rural blacks are still so inferior to that of the urban population, despite some improvement of rural conditions, that urban areas continue to exert a strong pull for people motivated to improvement of their status.

Beyond these generalizations it is difficult to go at this time. When the 1970 census results are in and we can see what changes have occurred in the size and composition of the black rural population, we shall be in a better position to judge the probable extent and nature of the future flow. There is no question that the vast rural-urban movement after 1940 was the major source of the rapid growth of black urban population and hence was a major contributor to those urban problems associated with black growth and congestion per se, but it was probably not critical to the changed politico-cultural mood and stance of the urban black population.

Most of the current further increase of the urban population is coming from natural increase rather than migration. This point is becoming publicly understood, as is the fact that black urban residents of rural origin were not disproportionately represented in the major riots of late years that stimulated so much belated interest in migration. The period when policy support for programs to benefit rural blacks—and thus perhaps retard migration—could be obtained from urban sources on a self-interest basis was rather brief in its life span. Cutbacks in rural-urban movement now, when the supply of migrants has been somewhat depleted, would be unlikely to have major beneficial effects on efforts to relieve urban congestion or otherwise improve the conditions of urban life.

Effects of Government Policies on Employment Opportunities for Blacks

George S. Tolley

Just to enumerate ways in which government policies affect employment of blacks calls for considering the entirety of local, state, and federal spending as well as a gamut of laws and other actions. Startlingly few findings are available on the impacts of the policies. Too frequently discussion of the disadvantagement of blacks does not seriously consider policy impacts but degenerates into debating whether to do nothing or everything. Everything includes, but is not limited to, fostering inflation, wage and related labor policies, civil rights measures, credit, black capitalism, education and training, health, housing, revenue sharing and welfare.

The present remarks consider impacts in a short space based on limited evidence available. Nevertheless, in place of a choice between nothing or everything they point definitely to a policy mix entailing, first, abandoning well-intentioned policies with adverse effects and, beyond this, focusing effort more sharply on certain policies offering hope of high payoff.

Employment and Inflation

The idea that blacks suffer disproportionately if there is an increase in total unemployment is germane here in the midst of the fourth major recession since World War II. Every recession is different, and this one has its full share of unusual features. After several years of success in maintaining a high level of employment, the danger finally materialized in the late sixties that aggregate demand increased rapidly for a time without being fully countered by offsetting fiscal or monetary measures. As a result, inflation accelerated and was found not to be readily slowable. Contributing to the recession that became pronounced in 1970 were federal expenditure reductions and the monetary measures taken to fight the inflation. An anomaly is that unemployment, wages, and the price level have all been rising rapidly at the same time. In the past two years, average gross hourly earnings have risen on the order of 6 percent per year, which is just about the same as the rise in the consumer price index [25, pp. S-8 and S-15]. Because of increasing productivity prices can usually be expected to rise 2 percent less than wages, even in the absence of a recession. In a recession one expects prices to fall further behind wages. The expected relation between prices and wages, which is contrary to recent events, emerges from models where wages are assumed to adjust more slowly than prices to changes in demand conditions. Recent models of this kind are found in the literature surrounding the Phillips curve controversy, in which an emerging view is that at best any trade-off between unemployment and inflation is temporary [7, 17]. Clearly the trade-off between unemployment and inflation is not as straightforward as customarily thought.

By historical standards recent events have been unusual in financial markets. In explaining high nominal rates of interest, expected inflation has rightly been emphasized [29]. A case can also be made that underlying conditions leading to higher real interest rates have also contributed to nominal interest rate changes. The most important lesson from recent financial events may lie in the simple fact that high and fluctuating interest rates have been survived without disaster, as have substantial readjustments in stock prices.

These recent events, leading to changes in views on stabilization, suggest needs for new monetary-fiscal policy combinations. A combination that can be recommended is to continue the newer active monetary policy focusing on control of the money supply to help avoid inflation, while at the same time pursuing tax and expenditure policies aimed at income, employment, and related goals. A commitment to perseverance in use of monetary policy to combat inflation would make it prudent at the present time to substantially increase expenditures of help to blacks. While the policy combination could lead to a continuation of relatively high and fluctuating interest rates, this is a minor cost compared to the gains in reduced inflation and increased overall employment from which blacks have so much to gain.

The policy suggestion just made runs counter to some long-standing views. On the other hand, an accepted view reinforced by the current recession concerns workers of low skill. Publicity

George S. Tolley is *professor of economics at the University of Chicago.*

has wrongly given the impression that this recession has been centered on middle class space age professionals. The contrast between experiences of white and blue collar workers is instructive. During the 12-month period ending in October 1970 white collar unemployment rose from 2.4 to 3.2 percent, and unemployment of blue collar workers rose from 4.2 to 7.2 percent. As usual, the concentration of effects has been among blacks, whose unemployment rate rose from 6.6 to 9.3 percent, and teenagers, for whom the rise was from 12.9 to 17.1 percent [25, p. S-13]. Reflecting a compounding of these last two rates, unemployment of black teenagers had risen to 30 percent by the third quarter of 1970 [26, p. 65].

How can these unemployment patterns be explained? Regardless of policies, the average level of unemployment from which any recession starts is relatively great for those less skilled workers who normally have short duration of employment on any one job. In an occupation where duration of jobs is short, more workers at any one time will be looking for a new job. On becoming unemployed less skilled workers probably do not search as effectively in unfamiliar industries and areas as those with more skills. Less skilled workers have fewer jobs of lower skill to turn to and are no doubt less apt at turning to jobs for which they do not have experience. Another reason why unemployment rises more for unskilled workers in a recession is what Lester Telser has called specific human capital (see [15]). Because skilled workers are more highly specialized to their jobs, the costs to employers from hiring and firing them are greater and at least partly explain why highly skilled workers are kept on while those with less skill are fired.

A villain that now enters is minimum wages. The accumulating evidence that minimum wages have deleterious effects on less skilled workers [5, 8, 14, 16] is consistent with a straightforward theoretical argument, namely wage above equilibrium. Tortuous lines of reasoning are required to escape concluding that minimum wages contribute to umemployment of less skilled workers. Similar remarks could be made about other labor policies and about some activities of unions.

Aside from the implication that further increases in minimum wages are undesirable, two more constructive policies are implied. Both are prime candidates for inclusion in the fiscal policy suggested above. First, blacks would gain much from an expanded and federalized unemployment insurance program to help cushion effects of employment fluctuations. Second, the effects of minimum wages give stronger reasons than ever for government expenditure programs aimed at increasing employment of less skilled workers.

So far, programs aimed at unskilled workers have emphasized training. In 1970 a manpower bill nearly became law that would have provided substantial federal funds to employ the workers [20]. A consolation in the delay is that time may be gained to improve design. The employment programs raise problems of slippage, efficiency, and logistics. The slippage problem is how to increase employment without incurring large expenditures for those who would be employed anyway. The efficiency problem is how to ensure that the expenditures result in a worthwhile product. Employment in health occupations is most frequently mentioned as a worthwhile focus. The logistics problem is how to organize so that jobs and people will mesh and so that the program will be self-liquidating if the need diminishes. A policy that rates high in ability to meet all three problems is a variable wage subsidy. The subsidy would apply to classes of workers identified each quarter as having high unemployment rates and would vary with their rate of unemployment. It could be restricted to certain industries and occupations, or it could be available across the board to any employer.

Spatial Impacts of the American System[1]

Much attention has been given to the tendency for employment to grow in suburbs and other places outside the central cities, while blacks remain concentrated inside central cities partly because of housing discrimination. One result of this spatial pattern is diminution in access of blacks to jobs, particularly for those without cars. Other results are lack of access to higher quality of education for children and to public services generally and a socially undesirable racial apartness with a growing spectre of black reservations ringed by white suburbs. There is lack of understanding of reasons for the spatial pattern, particularly in quantitative terms. Consequently, the effectiveness of pol-

---

[1] This section emphasizes blacks, whereas an earlier paper, "Implications of the Urban Crisis for Rural America" [24] was concerned with the way some of the same considerations affect rural people.

icies aimed at influencing the pattern is difficult to judge.

The spatial separation of blacks and whites has not yet been changed by civil rights policies in any overall way. According to Taeuber [21, p. 220], from 1960 to 1969 the central cities had an increase of black population of 2.6 million and a decrease of 2.1 million in white population; as a result, while blacks comprised 12 percent of the population of metropolitan areas in 1969, they accounted for 21 percent of the population of central cities and 5 percent of suburban rings. The major change since 1960 has been an increase in percentage of blacks in the central cities. According to Taeuber, "nearly three-fourths of the total national growth in the Negro population since 1960 has occurred in the central cities of the metropolitan areas." It is true that "available evidence indicates some increase also in the number of Negroes in the suburban areas, but the numbers involved are still so small that it is difficult to establish the size of this increase."

A full list of reasons for existing patterns extends far beyond policies overtly concerned with segregation. Movements of people are not directly controlled; but many community, city, and state decisions influence where people live. Incentives under this system affect resource allocation and income distribution in ways that can be understood by starting from a pure case and introducing successive complications. If all group expenditures were for public services paid by marginal user charges and, even more extremely, if people did not need to live near where they work, their choices of where to live would lead to clustering into communities where everyone desired the same bundle of public services. Each community in the country would consist entirely of residents who were exactly alike in their income and tastes. Between communities there would be complete stratification of people. The situation would be optimal from a resource allocation point of view. Tiebout, who emphasized this theory [22], was influenced by observing people choosing where to live among a variety of suburban communities. Unfortunately for the theory, differences among suburbs explain at best only a part of the variation in local public expenditure. Because travel costs limit the distance people live from work, because people of different income levels are complementary in production, and because there are economies of scale in a spatial context in supplying public services, the complete stratification envisaged in Tiebout's too simple world does not occur. People of differing income and tastes do in fact live within the same taxing and spending jurisdictions.

In spite of this complication, a resource allocation optimum might still be achievable for services financed by charging users extra costs of providing service to them. A concomitant complication to be considered, however, is the income distribution motive important in many public expenditures. Relief and welfare are outright income redistribution, and additional income redistribution is accomplished through collecting less in taxes than the costs of education and other public services supplied to poorer residents. It follows that the degree of stratification among communities will affect the degree of income redistribution. More redistribution is likely, the greater is the degree of income inequality within a community. Higher income people can avoid having income distributed away from them by segregating themselves into communities lacking poorer people, and the automobile has made this easier. Zoning and codes restricting the supply of housing demanded by lower income people are among the policies used by richer communities to exclude poorer people.

Financial incentives to move away and exclude people give impetus to a stratification of people beyond the point that is desirable for resource allocation or income distribution aims. People travelling far to work and in some cases being unemployed are examples of resource allocation costs resulting from efforts to avoid income redistribution. Even if the present degree of income redistribution is accepted as most desired, the redistribution could be achieved at less cost if carried out in a way that did not lead to the extra stratification now incurred to escape it. Studies of location of jobs and residences by race, e.g. [11], suggest that the potential cost reduction may be great. There is, furthermore, reason for believing that the costs incurred to avoid the burden of income redistribution lead to a less than optimum degree of income redistribution. Income redistribution is a public good and leads to free rider problems. People favor it, but everyone else shares in the good of one person's contribution. The social benefit from a person's contribution to income redistribution is thus greater than the benefit felt by the contributor. This view of income redistribution is implied by Becker [1] and Hochman [10], who have not, however, been

concerned with the spatial implications. If people were unable to move, community decision through local government could hope to avoid the free rider problem. Moving to another taxing jurisdiction is a way of avoiding the consequences of the community decision.

The discussion so far has concentrated on pocketbook motives affecting stratification of people into communities. Further reasons for believing there is overstratification have to do with people's tastes. Stratification is affected by the fact that people's satisfactions depend on who their neighbors are. As long as people's tastes are accepted, this influence increasing stratification need not be considered undesirable in itself, though it probably heightens the tendency toward a less than optimal amount of income redistribution. People's tastes have a public good quality. The collective outcome of these tastes may have undesirable effects which no individual has much incentive to take into account in his own acts. Attention has been given to the idea that people in their choice of neighbors exhibit racial discrimination. The view that racial discrimination is undesirable gives another reason to suppose there is overstratification. One could go further and postulate that to avoid separation of people into isolated groups the degree of mixing in communities of people of differing income and ethnic groups is a social end in itself. The idea that mixing is desirable, beyond the point to which it would be carried by people even in the absence of racial discrimination, provides yet another reason for believing local decisions lead to overstratification.

These remarks have stressed how expenditures below the federal level lead to an American style apartheid for both pocketbook and taste reasons. Federal expenditures also contribute to the apartheid. Federal income tax laws that encourage home ownership because of interest deduction in F.H.A. mortgage insurance have favored growth of single-family suburban housing for higher income whites who otherwise would have stayed renting in the inner city. A study by Wyatt Mankin indicates that the pronouncedly lower rate of home ownership for black than white families is explained for the most part by income and other nonracial characteristics, but some effect of the race variable is also evident suggesting discrimination [13]. The study suggests that the tendency for blacks to be bottled up in central cities is increased by black lack of financial resources for home ownership, relative to higher income families favored by federal government policies.

Condominium laws, making possible home ownership in multifamily structures, favor black ownership to some extent and allow whites to own in modern apartment buildings in the city center. Experimental subsidies for acquiring home ownership under Section 235 of the housing act undoubtedly encourage some greater degree of mixing of races by giving lower income blacks financial options to move into single-family neighborhoods. However, the mixing effect seems likely to be minor. The major effect may be to make for ownership rather than rental within predominantly black neighborhoods.

Federally sponsored public housing projects have led to greater isolation of poor people in areas within cities where thousands of people nearly all down and out live, in place of a situation where the housing would have been older but would have had a greater mixture of people of different income and social strata. Proposals for undertaking more of these projects in suburbs miss the point unless the need for changing their character is also recognized. The proposals for subsidies for low-income housing in suburbs do have something to recommend them over "stick" programs that make federal aid contingent on a "workable program" or have more overt sanctions. On the other hand, turning urban renewal into a low-income housing program will not do much to help blacks; for whatever else can be said about urban renewal, it encourages more mixing by making central cities attractive to higher income persons.

The major impacts of the federal government have just begun to be considered in this discussion. Effects of transportation policy, particularly urban expressways, have been twofold in opposite directions. By providing better access, expressways increase the possibility of speeding to and from work in the central cities while living in suburbs. On the other hand, the expressways have retarded decline of economic activity in the central cities, making for more city job opportunities for blacks and for tax revenues for public services benefiting central city blacks.

The largest spatial effects of the federal government may come from the discretion in the entire remaining part of the federal budget. In recent years the geographic impacts of de-

fense and space age spending have received publicity, but these provide only recent dramatic examples. There is establishment bias in the discretion used in deciding where federal expenditures will be made. The nuclear accelerator being built in Weston, Illinois, is illustrative. The accelerator was built in Illinois is illustrative. The accelerator was built in Illinois partly in order to try to disperse to the Midwest some of the federal science expenditures concentrated on the west and east coasts. In the decisions as to where within the Midwest to build the facility down to many details of construction, it appears that elites were involved whose interests prevailed over those of lower-income groups. This extended to the obliteration of the town of Weston itself, which was a low-income community [12]. This is a case history illustrating a principle.

The Gains to Blacks from Reducing Discretion

Since black power—evinced either through voting strategy or through protest actions—does not compare in strength to white power, blacks seem bound to lose in the game of discretion. A way to win is to play a different game. A promising approach is to have more government spending decisions made on the basis of quantitative estimates of contributions to objective criteria, reducing scope for discretionary decisions which tend to favor established people of influence and not blacks. Most federal expenditures are made now with no necessity for serious evaluation. The criteria should include contributing to national income. Employing persons who would otherwise be unemployed or, if employed, would be in less productive work is one way to contribute to national income. Several years of concern with Appalachia and other lower-income nonmetropolitan regions have led to development of techniques for estimating the contribution of spending to national income through reducing unemployment and underemployment [9, 23]. Application of these methods to all federal expenditures should result in increased employments of blacks, in view of the present concentrations of unemployment and low earnings among them. The increased employment in tax jurisdictions where blacks live would increase local tax revenues, enhancing local capacity to provide quality education and other public services. Recognition is needed that a goal is to achieve a higher degree of mixing of families of differing income and ethnic backgrounds, as emphasized in the preceding section. Meaning ful measures of degree of mixing can be con structed and estimated for all kinds of federa spending.

Each type of spending has its own evaluatio problems. For a discussion of a type of spendin for which objective evaluation has lagged, se the views of Richard Muth and myself in th recent report of the Presidential Task Force o Urban Renewal [18]. The Office of Managemen and Budget, as an instrument of the Presiden speaking for the nation and not for particula interests, could be empowered to require tha all federal expenditures be subjected to quanti tative estimation of impacts on national goals Responsibility for development and enforce ment of evaluation methods should be at centralized level with the executive branch t ensure uniformity and to protect against bia that creeps in if methods are left to agencie that identify with interests benefited by them Quantitative evaluation has by now becom sophisticated for some types of expenditures particularly water resource projects, as il lustrated recently in attempts by the Wate Resources Council [27].

There is at least equal scope for applying ob jective criteria below the federal level. A fur ther important benefit would be to increase th efficiency with which state, city, and com munity services of particular importance t blacks are carried out. The benefits would b especially great at the present time when de mands are increasing in the face of difficultie in raising revenues. The work of RAND fo New York City is an example of efforts o larger municipalities to bring more analysi into local government expenditure decisions Even for larger cities the surface has hardl been penetrated. For smaller municipalities particularly in the more rural parts of th country, a case can be made that more tech nical assistance is needed for community ex penditure decisions. Because each communit is too small to justify elaborate evaluatio studies, a pooling of efforts for planning o common problems appears justified. The plan ning is impeded by a lack of methods for es timating quantitatively the benefits of th gamut of local expenditures and would be a worthy focus of research effort.

Policy Mix

While the need for more objective evaluation of expenditures is great, even with the best

advances to be hoped for, gains to blacks from such reform could take a long time to materialize. More pointed and larger efforts are needed to improve their position in a reasonably short period. At the extreme of pointed efforts is the complex bag of stick programs epitomized by civil rights legislation providing for sanctions against discrimination in voting, housing, and employment. On net these measures have undoubtedly increased opportunities for blacks. A question of importance is how far they can be pushed without inviting more backlash than they are worth. Without increasing reliance on stick programs, the major way a near-term improvement for black opportunities seems possible is through increased spending. Several of the arguments made earlier come together to focus on revenue sharing. If carried out in a way to reduce disparities in public service levels among jurisdictions, it could help eliminate some of the apartheid tendencies inherent in the American system of public finance. A desirable approach would be to allocate federal funds on the basis of need, geared to the difference between the tax revenue people bring to a community and the local public expenditure for public services supplied to them. A corollary from the discussion of the desirability of objective criteria for spending is that the expenditures should carry requirements as to evaluation, using quantitative measures of contributions to national goals. These considerations suggest, then, not block grants to state capitals, but grants to communities within states according to needs, conditional on objective efficiency tests and provided for specific purposes.

In addition to the unemployment and wage subsidy programs mentioned, several other kinds of expenditures should be emphasized. The evidence becomes most meager when one tries to estimate where the highest payoffs in different kinds of public spending occur. In the absence of this evidence it may be hypothesized that in terms of contributing to national goals both of income and opportunity, human resource expenditures have a high payoff, as do to a lesser extent direct efforts to attain a more equal income distribution.

What Kinds of Human Resource and Income Distribution Measures?

The lack of knowledge about effectiveness of alternative approaches to improving human resources is almost amazing, given the many programs and experiments of the last ten years ranging from job training to federal aid to public education. It is true that the programs have been examined to the extent of revealing that the cost is high for a neighborhood youth program largely devoted to paying a living stipend rather than giving education and that a given proportion of trainees obtained a job at the end of training. These findings, however, do not permit reliable conjectures about the comparative contribution of programs of the last decade to national goals. Methods for doing deeper analyses are available, as illustrated in [2] and [4], but few meaningful studies are available that throw light on the comparative effectiveness of different approaches.

Estimates have been obtained indicating that returns to general public education are substantial [19]. A defensible hypothesis is that some of the most productive expenditures leading to better job opportunities for blacks would be on general primary and secondary education, with a broad interpretation given to the concept of education. While the delay in payoff of measures for children is longer than for adults, ten years is not a long time within which to make progress, given the magnitude of the problem.

The Coleman report [3] may be cited as an extensive study concerned with race and general education. It indicates that integration has a small but positive influence on student performance. Most important for the present discussion, socioeconomic background of parents is a chief explainer of school performance. If education is interpreted to mean preparation for life, the most overwhelmingly important part of education takes place in the home. The finding that socioeconomic background explains much variation in student performance suggests that education in the home and education as traditionally given in schools are complementary. An implication is that general education, if increased, should not simply give more of traditional kinds of education. Much of the lack of opportunity for blacks comes from cultural deprivation, which is to say a lack of education in the home. Public school expenditures that attempt to substitute at school things missing in the home environment have much to recommend them.

A characteristic of earnings of blacks noted by several persons, e.g. [6, 28], is that returns to education appear lower than for whites. Earnings tend to rise the more education a black has

had, but not as steeply as for a white. This pattern might be taken as evidence that the the returns from more general education would not be effective in increasing economic opportunities for blacks. Such an argument is justified if lower earnings of blacks are due to job discrimination. However, job discrimination is lessening, and there are two other reasons that may be more important in explaining the flatter education-earnings profile of blacks. Poor quality of education of blacks in the past could explain the lower returns if education is measured simply as years of schooling. Past concentration of black education in the rural South, where education expenditures per pupil are low and where there have been poor teachers perpetuating low quality, suggests that poor quality may be important in explaining apparently low returns to black education. The evidence then does not contradict the contention that there would be high returns to improving the quality of education of blacks. The hypothesis that there is complementarity between home and formal education could also help to explain the apparently low returns to education of blacks. Improving general education is the only approach among those reviewed in this paper that is directed at the major root of inequality for blacks, namely cultural deprivation.

If these arguments are accepted, income distribution measures are desirable but receive lower priority than education measures. Income measures can help to some extent to increase informal education in the home because more family income enables more education within the home, perhaps most directly in enabling the mother to spend more time with the children. However, income redistribution is a trickle-down approach to education and does little to upgrade the quality of the teachers in the home who are the culturally deprived family members.

Conclusion

Policies that would be favorable to blacks have been discussed here qualitatively. Expanding unemployment insurance and initiating variable wage subsidies would have rather immediate effects. Abandoning ill-advised labor policies may offer hope in a longer term. Also in the longer term, spatially equalizing expenditures having income redistribution impacts would reduce tendencies toward stratification harmful to blacks. Blacks should be helped by reduction in discretion in all types of government spending. Most hope rests in human resource programs with payoff in the intermediate term of, say, a decade.

Modest shifts in voting strengths could make possible substantially increased expenditures for programs discussed in this paper. Assuming such voting shifts eventually occur, what course will then be desirable? In view of the inadequacies of the evidence, there is much scope for disagreement. The prevailing estimates of respectable returns to education, in face of vast increases in education over the past several decades, give a presumption that returns would diminish little as a result of large expenditure increases. A subjective judgment is that a package possibly well over $30 billion that emphasizes education and manpower measures, with particular efforts to make up for home lacks, could dramatically improve the economic position of blacks and could be easily justified in terms of contributions to national goals.

Economic Position and Prospects for Urban Blacks

Phyllis A. Wallace

This report examines some current economic problems and prospects of urban blacks. Extrapolation of present trends on income and wealth, occupational distribution, etc., will not significantly narrow the black-white economic gap. In fact, there could be one kind of future for the middle class, educated, highly mobile blacks and another for that majority now isolated in the nation's ghettos. Their futures are one, however. The positive indications of this outcome are briefly sketched below.

Economic Problems

By most measures of economic well-being (statistics on size and distribution of income and wealth, employment status, entrepreneurial activity, etc.), blacks are substantially worse off than whites. In 1969, 71 percent of all blacks lived in metropolitan areas with 56 percent in central cities and 15 percent in the suburban rings. Blacks accounted for 21 percent of the total population in central cities and 5 percent of those in the suburbs. Slightly more than half of all blacks lived in the South with the latter group divided more or less evenly between metropolitan and nonmetropolitan areas [7, pp. 4–9].

The relatively poor economic status of blacks is associated with the following:

(1) Blacks constitute about 11 percent of the civilian labor force, receive somewhat less than 7 percent of aggregate money income, and have less than 2 percent of all assets owned by American households. In their examination of data from the Survey of Economic Opportunity, Brimmer and Terrell found that in 1966 the average net worth of white urban families ($19,278) was more than five times greater than the average net worth of black urban families ($3,407). The disparity in net worth revealed considerable understatement of the economic position of blacks [1].

(2) Blacks are at a serious disadvantage relative to whites in the labor market: They have greater underemployment and higher rates of unemployment, are less likely to be covered by collective bargaining agreements, and are in low-wage industries that offer the least opportunity for training and upgrading. It is surprising to note that there has been rejoicing because the ratio of the black to the white unemployment rate has dropped to less than 2 to 1 and that a disproportional part of the increase in joblessness has been borne by white collar employees and/or white workers. The unemployment rate for white adult male workers in SMSA's with population of 250,000 or more increased from 1.8 percent in the fourth quarter of 1969 to 3.9 percent in the fourth quarter of 1970. The rates for black males in these areas moved from 2.6 percent to 5.0 percent during the same period [8]. These aggregates may obscure unemployment of long duration and lack of labor force participation for blacks, especially in urban poverty neighborhoods.

(3) Black urban families are larger and a higher proportion of these families are headed by females. The proportion of black families in metropolitan areas headed by females was more than three times the proportion of white families headed by women [7, pp. 16–36].

(4) Despite high levels of economic activity in the mid-sixties and some improvement in the educational attainment of blacks, the relative income differences have not improved. In 1968 the income per family member for blacks was 55 percent of that of whites in metropolitan areas. If these observed income ratios are adjusted to reflect poorer net worth status, the per capita income for urban black families might be no more than 50 percent [4].

(5) In many cases attainment of moderate income levels for black urban families requires a greater effort. In 1968 the median income of black families with two earners was less than white families with a single earner ($7,910 compared to $8,422) in metropolitan areas. Within the black community the "talented third" make it into the middle class; the rest, greatly impoverished, lag far behind. Only 29 percent of black families in central cities, and with male heads, had income of $10,000 or more.

(6) Although some blacks residing mainly in suburban rings and smaller metropolitan areas

Phyllis A. Wallace is *vice-president for research, Metropolitan Applied Research Center, New York City.*

escaped from poverty during the period 1959–1968, blacks accounted for a larger proportion of the poor population in metropolitan areas in 1968 (32 percent) than in 1959 (29 percent). Children under 18 years old accounted for almost three-fifths of all poor blacks in metropolitan areas.

(7) Residential segregation creates a highly visible geographic separation which serves to maintain status exclusiveness. It also results in de facto segregation of black urban families in schools, restricts access to employment in outlying areas, and encourages overcrowding and deterioration which contribute to a high rate of disease and crime.

(8) Patterns of employment discrimination have not been significantly changed in most industries [9]. The 1967 report on job patterns for minorities and women prepared by the Equal Employment Opportunity Commission noted, "Not only was the overall minority representation slight, it was not significantly related to the degree of need for improvement. Industries where minorities enjoyed greatest increases in representation were not industries where their representation was lowest in 1966. Thus, the general pattern was for improvement to occur in industries where minority representation was already above average. . . . Disproportionately few officials and managers were members of minority groups. In the occupation where hiring, firing, and promotion and decision-making take place, minorities were even more underrepresented than in other white collar occupations."

(9) Blacks have been effectively excluded from significant participation in program resources of the public sector. The delivery of a full range of community services has not been equitable.

Prospects

Are the economic prospects for urban blacks as bleak as the present data might indicate? Thurow has noted that whites seek to maximize their economic gains from discrimination. These gains and the desire of whites to increase their social distance between the races are the major barriers to attaining black/white economic equality [5]. Despite the estimated 25-year lag of black incomes and the substantially poorer net wealth position of black families, some improvement of the economic status of blacks within the last third of this century may occur. This is a long-run view. It does not predict that parity in employment or income will be achieved in three decades, but only that some gains in the economic status of urban blacks may be associated with some specific structural developments.

I shall discuss only six positive indications of movement toward significant economic and social change for urban blacks. The list could be expanded and perhaps given some rank order in terms of extent of expected status improvement. Increased cohesion within the black community, the dynamics of the youth revolution, the growth of labor unions, the more perceptive socially oriented activities of business, diffusion of training techniques within the civilian sector of the economy, and the formulation of comprehensive long-term programs to upgrade the quality of life may produce beneficial results for blacks.

Ethnic cohesion.—With the recent intensification of racial polarization, blacks have started to define new modes of conduct relevant to their lives. Black caucuses in a number of organizations are manifestations of concern over group identity, status, and survival.

Youth revolution.—Erik H. Erikson's "Memorandum on Youth—Toward the Year 2000" noted that "the ethical questions of the future will be less determined by the influence of the older generations on the younger ones than by the interplay of subdivision in a life scheme in which the whole life-span is extended; in which the life stages will be further divided; in which new roles for both sexes will emerge in all life stages. . . . In the next decade, youth will force us to help them to develop ethical, affirmative, resacralizing rules of conduct that remain flexibly adjustable to the promise and the dangers of worldwide technology and communication" [2]. These rules of conduct may determine a more humanitarian acceptance of low-status individuals in this society. The economic consequences may precede the social reorganization.

Growth of labor unions.—I anticipate a much more positive role for trade unions in helping to advance the economic status of blacks. As blacks move into more highly skilled jobs or as they participate more fully in some of the growth sectors, particularly the service industries, unions will view them as likely recruits for membership. There has been considerable debate about the construction unions and their role vis-a-vis minority apprentices and journeymen. Surely within the social sci-

ence community someone could design a program to persuade the white journeymen of today that as their own sons and younger relatives move up into white collar jobs, they could pass the skills of the trade along to "apprentice sons" who would be minority youngsters and would not be a direct threat to their present jobs.

Socially oriented business.—Many employers who are locked into central cities and find it difficult to flee to the suburban fringe have started to investigate how they might best train and utilize the minority manpower now residing in these areas. For example, if some of the public utilities had anticipated a decade ago the problems and financial burden of recruiting and training both skilled and low-level white collar employees, they would have followed a different path to the 1970's.

Diffusion of training techniques.—There will be some diffusion in the civilian sector of techniques utilized to excellent advantage in the military. In 1966 the Department of Defense established Project One Hundred Thousand. The objectives of the program were to upgrade skills and improve education of large numbers of youngsters who would have been disqualified for military service because of their educational deficiencies. Almost a quarter of a million young men were accepted into the program by 1969, and about 40 percent were minority (mostly black) [3]. These young men were returned to civilian life with skills needed to pursue successfully a number of jobs. Their records should tell us much about on-job training and job performance.

Long-term program.—On December 31, 1970, the President signed the Housing and Urban Development Act of 1970 [6]. Title VII, the Urban Growth and New Community Development section, represents a major new resource for improved life opportunities for urban blacks. The Federal Government will assume responsibility for development of a national urban growth policy which should: (1) foster continued economic strength of all parts of the United States, including central cities, suburbs, smaller communities, local neighborhoods, and rural areas; (2) treat comprehensively problems of poverty which are associated with disorderly organization and rural decline; (3) refine the role of the Federal Government in revitalizing existing communities and in encouraging planned, large-scale urban and new community development.

The emphasis of this law will be on offering heterogeneous populations more choices for urban living. As centers for community services, environmental resources, economic and financial activity, and as focal points of political and socio-cultural values, new communities can offer blacks significant economic and social benefits.

Perhaps the most powerful forces noted above are noneconomic. I hope that economists will not become so enamored of sophisticated models that they fail to review their basic assumptions.

Research Notes

The Use of Discriminant Analysis in Selecting Rural Development Strategies*

DANIEL W. BROMLEY

IN THE Joint Task Force report entitled *A National Program of Research for Rural Development and Family Living* [3], we are reminded:

> Billions of dollars are being spent in the United States in attacking problems of families, communities, and the environment, and greater amounts may be needed in the future. In both current and projected situations, funding and program measures are being pursued without the required research and evaluation for effective and efficient policy formulation and direction. Scores of millions of dollars could be saved or used more effectively with measures based on the fundamental knowledge which research can furnish [3, p. 1].

The central theme of this paper is that one area of "required research for effective and efficient policy formulation" concerns the need to help those rural areas interested in increased economic activity to identify the most *feasible* of the range of *possible* strategies that they might pursue. It seems that much less research has been conducted on what is feasible for a community to achieve than has been conducted on what the residents of that community want to achieve. While local support is necessary for bringing about increased economic activity, it is not sufficient.

In the following I shall illustrate how discriminant analysis can be of use in assisting rural areas to discern their comparative advantage. Prior to treating the actual problem it is necessary to describe, very briefly, the essence of discriminant analysis.

Discriminant Analysis

Discriminant analysis has grown out of interest associated with assigning an unknown object to one of G mutually exclusive groups on the basis of a set of n measurements on that object [9]. Instead of analyzing data to decide in which group an individual or object will be superior (perform best), the problem is concerned with deciding which group an object or individual is *most like*.[1] For the former, regression analysis is appropriate; for the latter, discriminant analysis is relevant; the group to which an object or individual belongs is paramount, rather than some measure of relative efficiency within the group.

In 1936 R. A. Fisher hypothesized that a linear function, y, of the variables x_i $(i=1, 2, \cdots, n)$ such that $y=v_1x_1+v_2x_2+\cdots+v_nx_n$, would be a function capable of discriminating among groups [2]. The coefficients (v_i) of the linear function y are computed so that the ratio of the sums-of-squares between group means to sums-of-squares within group means is maximized. This ratio can then be used as a basis for a test of the hypothesis that the two points representing the position of the n means of the groups in the n-dimensional space occupy the same point for the populations under consideration. The linear function that maximizes this ratio is the discriminant function. There is no other linear combination of the

DANIEL W. BROMLEY *is assistant professor of agricultural economics at the University of Wisconsin.*

[1] Some relevant applications of discriminant analysis have recently been conducted by Blood and Baker to help classify ranches in the northern Great Plains between "wheat" and "cattle" [1]; by Prescott and Lewis, to analyze locational incentives among various areas [6]; and by Reinsel, to classify potential F.H.A. borrowers [7].

n variables which has the discriminating power of this one function [8, 9].

To be less abstract, assume there are two groups, A and B, containing N_g ($g=1, 2, \cdots, k$) objects each, with each object being scored on each of n characteristics. Upon computing the discriminant function for this set of objects,[2] at least two interesting analyses can be carried out. One possibility is to measure these same variables on an object of uncertain group identity, substitute these values into the discriminant function, and, based upon whether $y \lessgtr y^*$, place the object in the appropriate group (A or B).[3] That is, if $y > y^*$ the object most resembles those objects in group A, while if $y < y^*$ it most resembles those in group B. The second possibility is to compute the "scaled coefficients" to discern the relative importance of the variables $x_1, x_2, \cdots, x_n$ in discriminating between membership in group A or B. That is, one can rank the n variables in descending order of their relative contribution to determining proper group membership.

There are other statistical tests that can be conducted, but these two are of immediate relevance.

Empirical Application

The problem of discerning the subset of feasible alternatives for a group of rural communities can best be illustrated by restricting the range of choice. That is, the approach here will be limited to illustrating how discriminant analysis can help distinguish between "recreation" and "industry."[4] As a starting point, the 72 counties in Wisconsin were ranked on the basis of proportion of wholesale and retail services classified as catering to recreation users[5] and on the basis of per capita income derived from manufacturing.[6] The 11 counties with the largest proportion of the former index were combined into a "recreation" group (R). For the latter ranking, the top 20 counties were not included here since they comprise the highly industrialized counties along Lake Michigan. The following 17 counties were defined as being not highly urbanized or industrialized, yet as having achieved certain success in attracting industrial activity. These will be called M.

There are hence two mutually exclusive groups of counties, one group oriented primarily to servicing recreationists, the other consisting of primarily rural counties that have managed to attract some industrial activity. Because the dominant forces in achieving some greater degree of economic activity usually are in attracting tourists or industry of some kind, an important issue is to help aspiring counties to decide which route is most feasible for them in terms of a greater probability of success and, by implication, which group (R or M) they *most resemble*.

The first step in analyzing the current problem is to develop the criterion by which inferences can be made as to which group, R or M, an individual county most resembles. To accomplish this, 20 variables were hypothesized as possibly having a bearing on a county's presence in group R or M, and each of the 28 counties was scored on these variables.[7] These variables appear in in Table 1, along with two coefficients to be explained below. The column "discriminant function coefficients" contains the coefficients for a linear function $y = v_1x_1 + v_2x_2 + \cdots + v_{20}x_{20}$, which were so computed that the ratio of the sums-of-squares between group means to the sums-of-squares within group means is maximized. That is, there is no other possible linear combination of the 20 variables that will discriminate between groups R and M with the same level of confidence as y.

Once the discriminant function has been derived from the sample of counties in the two groups, it is possible to select a county not in-

[2] There will always be one less discriminant function(s) than there are groups to discriminate among. See [8].

[3] y^* is the "critical value" of the discriminant function. With three groups, there would be two discriminant functions and two critical values, with four groups there would be three functions and as many critical values. To compute y^*, the overall group means are substituted into the discriminant function for the x_i's.

[4] It is possible to expand the range of possible choices to more than two; this will be elaborated upon below.

[5] More specifically, this is the number of hotels, motels, tourist courts, camps, and amusement and recreation places as a proportion of the number of total service establishments. The difference consists of personal services, miscellaneous business services, auto repair, miscellaneous repair service, and motion picture theaters [5].

[6] That is, value added by manufacturing on a per capita basis [5].

[7] For those inclined to denounce this as inductive empiricism, Northrop [4] would be instructive. He effectively destroys the myth that there is but one "scientific method" and argues persuasively that the scientific maturity of the particular intellectual endeavor defines the appropriate method. For those "young" endeavors still searching for deductively formulated theorems, Northrop calls this the "natural history stage" of inquiry. Its components are primarily observation, description, and classification.

Table 1. Variables for 28 Wisconsin counties with the discriminant function coefficients and the scaled vector coefficients

Variable number	Discriminant function coefficients	Variable	Scaled value
1	.21	percent of land in forest	22.35
2	−.07	allowable cut/forested acre	−14.49
3	.20	distance to nearest city of 25,000–100,000	36.34
4	−.01	distance to nearest city of 100,000–250,000	− 1.45
5	−.12	distance to nearest city of >250,000	−26.90
6	−.15	through traffic volume	− 9.30
7	.03	distance to nearest Interstate highway	9.09
8	.00	acres of lakes in county	4.65
9	−.01	miles of trout streams in county	− 6.43
10	.25	percent of county land in public ownership	17.81
11	−.00	value of agricultural products sold	− 5.21
12	−.14	distance to nearest 4-year campus	−15.15
13	−.12	distance to nearest 2-year campus	−14.32
14	−.02	distance to nearest vocational school	− 1.73
15	.48	distance to nearest major health center	37.84
16	−.47	distance to nearest major airport	−44.89
17	.33	distance to nearest shipping port	44.95
18	−.45	distance to nearest ski area	−29.08
19	.12	distance to nearest major recreation site	14.16
20	.05	per capita tax levy	6.27

cluded in these two groups, one for which information is desired on its most feasible strategy, and score it on the same 20 variables. Substituting these values into the discriminant function, that county receives a discriminant score (y_i). The next step is to compare this with the critical value of the discriminant function, y^*. The critical value is computed by substituting overall group means into y for the x_i's. If $y_i > y^*$, the county in question most resembles those in group R; if $y_i < y^*$, it most resembles those in group M. For the present problem, $y^* = 15.59$.

Discriminant analysis can also indicate which of the 20 variables are most important in determining a county's resemblance to the two groups. The scaled coefficients in Table 1 indicate which variables have relatively more influence in placing a county in its appropriate group. The largest positive-valued coefficients, variables 17, 15, 3, 1, 10, and 19, are most important in placing a county in R; the largest negative-valued coefficients, variables 16, 18, 5, 12, 2, and 13, are are most important in placing a county in M.

Implications

To recount briefly, rural areas in search of greater economic activity have a range of possible strategies they might pursue. Among these there is one strategy which, on the basis of its particular set of characteristics, a given region may pursue with the greatest probability of success.[8] Additionally, discriminant analysis can indicate which of the variables measured were of greatest weight in placing the region in its "proper" group. By implication, then, it also indicates the most significant variables for placing it in another group. That is, as in the example here, if a region were "assigned" to group R but its residents wished instead to attract manufacturing, they might safely conclude that the addition of a nearby major airport (variable 16) would be the most important factor for moving them into (making the region resemble those in) group "M."

While the problem was here illustrated as a binary choice, it is possible to have three choices, say "one-day recreation," "overnight recreation," and "long-term recreation." Then the scaled coefficients would indicate the necessary attributes to enable a region most like those with "one-day recreation" characteristics to become most like those able to induce people to stay for one or more nights. Addi-

[8] When discriminant analysis is used to advise entering college freshmen which "career group" they most resemble there is nothing that indicates effective demand for their services. Likewise, its use here abstracts from the issue of "regional demand" for recreation services or manufacturing sites. The determination of comparative advantage by using discriminant analysis may be thought of as fulfilling the necessary conditions for greater economic development, but nothing more. The sufficiency test requires knowledge of regional excess capacity (or lack thereof) in providing recreational services and the knowledge of "footloose" industries seeking new locations.

tionally, more than one set of strategies might be employed in which recreation potential is represented by one continuum and industrial potential by another ("labor-oriented" vs. "materials-oriented"). This would indicate which of the various types of recreation enterprises and industry groups the region possessed the greatest comparative advantage for, based upon other regions' success in these various groups.

In conclusion, there is no pretense that this is a definitive work in the effort to identify the comparative advantage of Wisconsin counties.[9] The intent has been to call to the attention of scientists working in the general realm of rural development a statistical technique long used by educational psychologists for telling entering college freshmen which of five or six career groups they *most resembled;* that is, alerting the student to *his* comparative advantage. The hypothesis here advanced is that this problem is not unlike those of rural communities seeking some degree of increased economic activity. Just as discriminant analysis is useful in the former endeavor it can be useful in the latter as well.

[9] The indices used here are not the result of extensive literature review but were selected as ones easily obtainable through secondary sources, for the sake of example.

Analysis of Milk Production Costs Using Cross-Section Data: The Problem of Converting Observed Quantities of Milk to a Standard Butterfat Content*

J. Bruce Bullock

Analysis of milk production costs using cross-section data is complicated by the need to convert observed quantities of milk to a standard butterfat content. This need arises because the market price per hundredweight of milk is a function of its butterfat content. In other words, the market treats milks of different butterfat levels as if they are different products. Meaningful analysis of costs can be developed only for standardized units. Calculation of average production costs per hundredweight of milk using unadjusted quantities is not unlike estimating the average cost of producing a unit of automobiles and horses.

This problem has been widely recognized by economists. Few, if any, analyses have failed to convert observed quantities to standard units. The fat corrected milk (FCM) procedure developed by Gaines [2] is widely used by economists for this purpose. This procedure, however, compounds the problem it is intended to solve and introduces a bias into the cost analysis. The purpose of this note is to demonstrate the nature of this bias and to suggest a more appropriate standardization procedure for use in economic analysis.

The butterfat level selected as the base is arbitrary. This selection, however, defines the quantity adjustment factor to be used in the ensuing cost analysis. Once the base butterfat level is selected, only one price is relevant in calculating total and net revenues—the blend price of the base level milk. Moreover, total revenue on farm i, TR_i, is an observed quantity. Its value is unchanged as a result of the ex post facto and arbitrary selection of a unit of measure for milk. Therefore the implied total revenue (blend price of base level milk$\times$adjusted quantity) must be identical with the observed total revenue.

The constraint can be expressed as follows:

$$(1) \qquad P_kQ_i^* = P_k rQ_i^j = P_jQ_i^j = TR_i$$

where

k is the base butterfat content

P_k and P_j = the price per hundredweight of k and j percent butterfat milk, respectively

$Q_i^* = rQ_i^j$ = quantity adjusted to standard base, k percent hundredweight

Q_i^j = observed quantity of j percent butterfat content milk on farm i

r = quantity adjustment factor, and

TR_i = total revenue on farm i.

It is clear from the above identity that the adjustment factor, r, must be P_j/P_k. Any other adjustment factor will yield a different implied total revenue and the results will no longer be consistent with observed data.

Given k percent butterfat as the base, $Q^* = (P_j/P_k)Q_i^j$ is the unit of milk on which the market calculates returns (i.e., total revenue $= P_kQ^*$). Therefore, unless average and marginal costs are calculated for the same units, comparison of per unit costs and returns are meaningless.

The overriding constraint on a standardization procedure used in economic analysis is that it not distort measures of economic efficiency. In particular, the relative efficiency of alternative economic activities should be no different after standardization than in the original data. Cost per dollar value of output TC/TR is a measure of economic efficiency. Clearly, any adjustment procedure for which implied total revenue does not equal actual total revenue will lead to changes in the efficiency indicator. The price ratio adjustment procedure is consistent with identity (1) as shown above and thus leaves the original efficiency ranking unchanged. It is now shown that the FCM procedure biases the efficiency indicator in favor of milk with butterfat content above the base level. The FCM procedure involves selecting some butterfat content (k) as the base (e.g., 4.0 percent) and converting the observed quantities to k percent FCM units [4]. For example, 100 pounds of 3.5 percent milk would be converted to Q' units of 4 percent FCM as follows: $Q' = 100(.4+.15(3.5)) = 92.5$ pounds. Thus on an

* The helpful comments of Bob Wells, Richard Perrin, R. A. King, and Loren Ihnen on earlier drafts of this note are greatly appreciated.

J. Bruce Bullock is *assistant professor of economics at North Carolina State University.*

FCM basis, 100 pounds of 3.5 percent milk is equivalent to 92.5 pounds of 4 percent milk. By comparison, the price ratio method (using 1969 blend prices for North Carolina) defines

$$\frac{\text{blend price 3.5 percent milk}}{\text{blend price 4.0 percent milk}} \times 100 = \frac{7.0864}{7.3864}$$

$\times 100 = 95.4$ pounds of 3.5 percent milk to be equivalent to 100 pounds of 4.0 percent milk.

Thus, although 100 pounds of 2.5 percent milk has the net energy content of only 92.5 pounds of 4.0 percent milk, it has 95.4 percent of the value of 100 pounds of 4.0 percent milk.[1] The FCM procedure clearly discounts milk on the basis of butterfat content at a different rate than the pricing mechanism. As a result, average and marginal costs calculated on the basis of FCM units result in biased estimates of net returns because costs and revenues are measured in different units. Only if the market discounts milk solely on its net energy content will the two procedures be identical.

The possibility of pricing milk on the basis of its protein and nonfat solids content in addition to (or in lieu of) butterfat continues to be discussed. If these changes are adopted, the FCM procedure will clearly be useless for economic analysis since it would reflect only one physical dimension of the product. However, the price ratio method will correctly reflect all *economic* dimensions of the product regardless of the basis of the discount.[2] Thus, the price ratio method will continue to be a valid adjustment procedure for economic analysis. Any attempt to develop a standardization procedure based on the physical dimensions of milk will lead to biased cost estimates similar to the FCM procedure unless the pricing mechanism perfectly mirrors the physical relationships.

[1] The adjustment factor defined by the price ratio procedure will of course differ for each market. North Carolina prices are used only as an example. The fact that the adjustment factor will differ between points that have different prices is of no consequence. Comparisons of these points can be made by taking account of the differences in their price ratios. A more detailed comparison of the two adjustment procedures using data on North Carolina dairy farms can be obtained by writing to the author

[2] After this note was developed I found a study that used the price ratio procedure to adjust quantities [3]. The FCM procedure continues to be used, however (see [1]).

Use of Linear Programming in Capital Budgeting with Multiple Goals*

Wilfred Candler and Michael Boehlje

Capital budgeting is concerned with choices among alternative investment opportunities. These investment opportunities include not only business decisions, such as which plant to build and hence which new technology to adopt, but also the amounts to be spent by government on roads, education, research, military facilities, and the like. Given this wide definition of investment alternatives, capital budgeting can be seen to be one of the most important economic activities in both the private and public sectors.

Capital budgeting decisions almost invariably involve multiple goals, whether they are made in the public or private sector. The existence of multiple goals plus the difficulty that one man or even the several members of a management team may have in comprehending all the implications of all the available alternatives calls for the utilization of a systematic methodology in making capital budgeting decisions.

The use of linear programming as the systematic methodology to assist in the analysis of capital budgeting problems has been suggested by Baumol and Quandt [3] and Weingartner [7], among others. These authors did not, however, discuss the ubiquitous problem of multiple goals in capital budgeting. In this paper, we propose to extend their work by developing a method of solving capital budgeting problems that involve multiple goals.

It should perhaps be emphasized that the use of linear programming does not allow a reduction in the work of budgeting the detailed implications, particularly the cash flow implications, of alternative investment decisions. Budgeting, if done comprehensively, is extremely time consuming, since for each possible physical investment there may be several alternative ways of financing the investment and accounting for it for tax purposes. Each of these combinations of investment, financing, and accounting will have a different impact on the firm's after-tax cash position; hence each has to be treated as a separate investment alternative.

Conscientious budgeting of investment alternatives, however, will not lead to automatic selection of the "best" set of alternatives. A conceptual framework is also required to deal with these questions:

(1) How should the firm reconcile its conflicting goals?
(2) How should investment indivisibilities be handled?
(3) How far forward should investments be budgeted?
(4) How should price and technical variability be handled?

Only the first question relating to goals is considered in this research note. Since some goals cannot be brought directly into relationship with the measuring rod of money, a method is proposed to measure these nonmonetary goals. A linear programming model is then introduced and an adaptive "black box"[1] technique suggested to reveal the decision maker's preference function with respect to the multiple goals. An orderly search procedure is then introduced to permit estimation of the "efficient" capital budgets that would result from changes in the preference function. An efficient capital budget is defined as one for which it is impossible to increase the score of any one goal without lowering the score of some other goal.

The Problem

In general, capital budgeting with multiple objectives can be expressed as an integer nonlinear programming problem: Find the $1 \times k$ vector of activities and investment levels x, such that:

$$Z = z(g_1(x), g_2(x), \cdots, g_n(x)) \quad \text{a max} \tag{2.1}$$

subject to:

$$h_i(x) \leq 0 \tag{2.2}$$

Wilfred Candler is *professor of agricultural economics at Purdue University.* Michael Boehlje is *assistant professor of agricultural economics at Oklahoma State University.*

[1] The term "black box" is used for any procedure for converting input into output when the actual procedure for making the conversion is either unknown or unimportant. The term "adaptive" implies some element of feedback, so that each lot of output from the black box allows us to define a "better" set of input.

and

$$(2.3) \qquad x \geq 0$$

and some elements of x integer,
where

$g_j(x)$ the jth goal function; $j=1, \cdots, n$,
$h_i(x)$ = the ith restraints on the investment alternatives and resulting cash flows; $i=1, \cdots, m$,
$x = k \times 1$ vector of investment alternatives and investment levels, and
Z = some function, probably nonlinear, of the level of individual goal functions.

If the individual functions, $g_j(x)$, $h_i(x)$, and the objective function, Z, are known a priori, the capital budgeting problem can be analyzed by any of the complicated search procedures suitable for integer nonlinear programming.

We are concerned with the less general case in which (1) the restraints on the investment possibilities (2.2) can be expressed as, or approximated by, linear inequalities; (2) the individual goal functions, $g_j(x)$, can be expressed on an arbitrary linear scale; and (3) a local maximum of the objective function (2.1) is the global maximum and the direction of improvement of the function can be determined at any point.[2]

The first of these qualifications implies that restraints (2.2) can be replaced by a set of linear inequalities:

$$(2.4) \qquad Ax \leq b$$

where

A is a $m \times k$ matrix of the cash flows and flows and technical coefficients of the investment alternatives, and
b is a $m \times 1$ vector of restraints on the cash flows.

The second of these qualifications, that $g_j(x)$ can be expressed on a linear scale, presents few problems when the goal function is one that is typically measured in monetary terms. All that is required is that the function be linear in money, or that \$50 has a utility exactly five times that of \$10.[3] When the goal function cannot be easily measured in monetary terms, an arbitrary scale must be devised. This scale must meet the requirement that if we designate specific "bad" and "good" outcomes of the jth goal as, say, 0 and 100 respectively, then any other outcomes can be placed on the resulting scale and the preferences thus expressed are additive.

Suppose, for example, that one of a firm's objectives is to minimize pollution, and there are two investment alternatives: (1) a large sewage installation that would *improve* water quality leaving the plant, and (2) an addition to the plant that would not affect water quality leaving the plant but would add to air pollution.

The arbitrary scale might then assign 0 to do nothing (adopt neither project), and -100 to the air-polluting project. We then require that the improved water quality project can be placed, say, as $+20$ on the resulting -100 to 0 scale and that if *both* projects are undertaken their results would be additive on the scale (or $-80 = -100 + 20$).[4]

It is important to note that in the above example the two projects do not need to fall on any technical or financial continuum. The improvement in the "pollution level" resulting from improved water quality is not technically comparable with the decline in the pollution level because of increased air pollution. What we require here is a judgment by the decision maker that from the pollution viewpoint the deterioration in the environment caused by the air pollution project would be five times the magnitude of the improvement in the environment achieved by the sewage treatment project. This judgment is made in only the "one dimension" of the level of pollution. The decision maker need not determine which of the two projects he prefers overall; he has only to order

[2] That is, given any solution, x^*, the corresponding gradient vector:

$$v_x^* = \left[\frac{\partial z^*}{\partial g_i}\right]$$

can be evaluated. Note that we have not assumed that (2.1) itself is linear, merely that a gradient vector can be obtained and that a local optimum is a global optimum.

[3] Not all monetary goals will necessarily fulfill this simple requirement. It may be that \$5 million is not thought to be exactly five times as worthwhile as \$1 million. In that case even the monetary goals will need to be converted to a linear scale, as discussed below.

[4] Nonadditivity can easily be handled by defining mutually exclusive investment opportunities. If, in the example cited, the two projects gave a pollution score of -60 (rather than -80) on the established -100 to 0 scale, we could define *three* investment projects: (1) sewage plant, as before (score $+20$); (2) air pollution, as before (score -100); (3) sewage plant and air pollution (score -60); with the added requirement that, at most, one of these projects might be selected.

them linearly with respect to the particular goal currently under discussion.

The procedure calls for linearizing (or scoring on a 1 to 100 scale) each goal function, one at a time and in isolation. We are not at this stage judging any desirable trade-off between goals. It may be that with a total pollution "score" of 5000, the decision group would willingly pay $1 million to reduce the score by 100, even though with a total pollution score of 1000 they would pay only $.1 million for a further reduction of 100. The estimation of appropriate weights (in the light of the level of the goal fuuctions) is a major concern of this research note and is discussed below.

If the decision maker cannot provide even a tentative estimate of this "one-dimensional" information, it is obvious that the derivation of anything approaching an optimum capital budget would be extremely difficult. Certainly it would lie outside the scope of this paper.

The third qualification, that the direction of improvement of the objective function (2.1) can be specified at any point by the decision maker, enables us to use a search procedure to derive a sequence of improved capital budgets. The related assumption, that a local optimum is a global optimum, ensures that the terminal point of such a sequence will be the global maximum. If there are several local optima or the decision maker cannot specify the direction of improvement of the capital budget, the problem would likely require a very sophisticated model rather than the conceptually simple model proposed here.

Definition of Goals

The goals of the capital budgeting problem may be set by an individual or a group;[5] but in practice, a group or committee is likely to have much more difficulty than an individual in defining goals. As a basic procedure, therefore, it is suggested that several appropriate goals be agreed upon, an arbitrary but appropriate scale established independently for *each* goal, and individual projects then numerically scored in terms of their effect on *each* of these goals. For a planning committee of a company, for example, it is plausible that in addition to "profit" (probably itself a multidimensional concept), the group might agree upon the goals of minimizing pollution, improving the company's community relations, and increasing the company's technological sophistication. For each goal, two basing point projects would be clearly defined and assigned, say, scores of 0 and 100. All other projects would then be scored in terms of the arbitrary scale thus established. There is, of course, no need to use the same basing point projects to define all scales; rather, projects that have a dramatic effect on the particular goal should be used. Building a sewage plant would likely be a relevant basing point on the pollution scale, whereas sponsoring an athletics team might be an appropriate basing point for the community relations scale.

Reaching agreement on scoring of projects on the established scales is bound to be a major task involving disagreement and compromise. No claim can be made that establishing these scores is likely to be simple; it is claimed only that the suggested procedure provides at least some hope that the team will arrive in roughly the right ball park. Disagreements can arise among the committee members over the contributions of different projects to specified goal functions or because the goal function may encompass incommensurables, such as air and water pollution, on the same scale. If a serious conflict arises in the definition of the goal functions, it may be resolved in one of two ways: (1) expanding the number of goal functions to achieve a set for which reasonable agreement on scaling can be achieved; or (2) accepting more than one scaling of the goal function and running the capital budget for each scaling.

Both suggestions really involve shifting the conflict from the specification of the problem to the interpretation of results. If, for example, the pollution goal is replaced by separate water pollution and air pollution goal functions and agreement on the scaling of these functions is achieved, a conflict may still arise later as to the relative importance of these two goals. In the same way, if different scalings for the pollution function are accepted, conflict may arise as to which of the resulting capital budgets is the best. By delaying a decision on the relative importance of competing goals until trial capi-

[5] We note that we desire only to approximate the goal function set for the group of people actually able to make the relevant capital budgeting decisions. Thus, the fact that other people, in other situations, would rank outcomes quite differently is irrelevant if they have no power to affect the actual decisions under examination. When the preferences of other individuals can be imposed (by local or federal regulations for example), these outside preferences will usually be expressed as restraints on the capital budgeting alternatives.

Table 1. Schematic representation of simplex tableau for capital budgeting

Objective: Maximum		0	0	⋯	0	0	0	⋯	0	⋯	1	λ_1	λ_2	λ_3
		ACTIVITIES[b]												
Restraint[a]	B	Project 1.1	2.1	⋯	Bank	Project 1.2	2.2	⋯	Bank	⋯	Cash	Dividend	Asset	Pollution
Initial cash	100,000 ≥	2000	7000	⋯	100	0	0	⋯	0	⋯	0	0	0	0
⋮														⋮
Tax-free $cash_1$	50,000 ≥	−500	2000		−103	2000	7000		100		0	1	0	0
Tax-free $cash_2$	−10,000 ≥	−700	−10000		0	−500	2000		−103		0	2	0	0
Final cash	0 ≥	−1000	−10000		0	−700	7000		0		1	0	0	0
Final assets	0 ≥	−1500	−5000		0	−1000	5000		0		0	0	1	0
Pollution	0 ≥	−20	100		0	−20	100		0		0	0	0	1

[b] For i·j indexes on projects, i indicates the project number and j the year it is initiated.

tal budgets are available, it is hoped that the chances for agreement will be enhanced. It is easier to choose between two alternatives than to provide a comprehensive set of decision rules for making the choice.

In summary, the simple specification of relevant linear goal functions should not be an insuperable task, even for a committee. In any case, if consideration of the resulting capital budgets convinces the decision makers that they have misspecified their objectives, they can always reinitiate the analysis using more appropriate goal functions.[6]

Profit as a Multiple Goal

The discussion has concentrated on multiple goals that cannot easily be brought directly into line with the measuring rod of money. It is perhaps worth pausing to point out that, in the context of capital budgeting, profit itself is a "multiple goal." It is reasonable to suppose, for instance, that the following four frequently conflicting objectives are components of the traditional goal to "maximize profits":

(1) Maximization of the dividends paid to shareholders;[7]

(2) Maximization of "net tax free cash" available to the firm at the end of the planning period;

(3) Maximization of the value of assets owned (or controlled?) by the firm at the end of the planning period; and

(4) Minimization of the probability of financial collapse of the firm during the planning period.

Thus, *a firm cannot avoid the problem of multiple goals in capital budgeting by deciding to concentrate on the "single" objective of profit maximization.*

Similarly, much of the argument on the best single criterion for capital budgeting is irrelevant: The *n* dimensions involved in the objectives of capital budgeting cannot be mapped into a single dimension by any simple transformation such as payback period, internal rate of return, or even discounted cash flow. For this reason some discussions of the best (single) criterion for capital budgeting are reminiscent of the theories advanced by two-dimensional Flatlanders, when faced with a three-dimensional object [1].

Linear Programming

The capital budgeting problem can now be formulated in a multiperiod linear programming framework modified to accommodate multiple goals. The programming tableau is illustrated in Table 1. Four goal functions are included in this formulation: dividends paid to shareholders, net tax-free cash at the end of the planning horizon, value of assets owned at the end of the planning horizon, and pollution.

It is assumed in the illustration that two investment projects and the opportunity to put cash in the bank are available activities in each period (projects 1 and 2 in this illustration

[6] If King Midas had had the advantage of modern computer analyses available to him, he probably would have put some side conditions on his goal of being able to change things to gold after seeing the results of his first "run."

[7] Even this objective can be interpreted in a number of ways, since dividends are paid in different time periods (not to mention cash or stock) and different people may have different time rates of discount for future dividend payments.

refer to the sewage installation and plant addition discussed earlier). Activities are also included to accumulate dividends, final cash, final asset value, and pollution levels generated by the program. The final cash, final asset value, and pollution activities are constructed so that these activities take one unit of cash, assets, or pollution from the appropriate row and reflect it in the objective function. The dividend activity can be structured in a number of ways, depending on the firm's objectives. In Table 1 it has been assumed that the B column includes the cash withdrawal needed to maintain dividends at their present levels.[8] Thus, the dividend activity indicates *planned increases* in the level of dividends, and the firm wishes any such increase to be scheduled at a steady (linear) rate.[9]

The restraints included in the model refer to initial cash availability; tax-free cash at the end of years 1, 2, 3, etc.;[10] and final cash, final asset value, and pollution levels at the end of the planning horizon.[11] The B column interfaces the capital budgeting decision with the other operations of the firm. The coefficients in this column reflect the projected cash surpluses that would be generated in future years by the *current* level of capital stock minus cash withdrawals for dividend, tax, and overhead payments consistent with current policies. Thus, the firm has $100,000 of cash at the beginning of the planning horizon, and it is expected to generate $50,000 in year 1 and to want to withdraw $10,000 in year 2 with the current level of assets.[12]

After-tax cash flows resulting from any particular investment alternative can be represented as technical coefficients in the tableau.[13] The after-tax gain in cash deposited in the bank is set at only 3 percent, on the assumption that the difference between 3 percent and the bank's interest rate is taken in taxes.

The objective function in Table 1 includes only four nonzero entries, one for each of the four goal functions. The entries λ_1, λ_2, and λ_3 refer respectively to the weight the firm attaches to increasing the dividend payment, final asset value, and decreasing the pollution level, relative to increasing the amount of final cash.

An Adaptive Black Box

The linear programming procedure described above will yield an efficient solution to the capital budgeting problem for any levels of λ_1, λ_2, and λ_3, the relative weights assigned to the goal functions. As defined here, an *efficient solution* is achieved when it is not possible to improve the score of any one of the individual goal functions without lowering the score of at least one of the other goal functions. Even given that an efficient solution can be obtained, there is still the problem of deriving the efficient solution preferred by the decision maker or decision-making unit, which amounts to using the right relative weights (such as λ_1, λ_2, and λ_3) in the objective function.

The approach proposed here is an iterative approach using both the decision makers and the linear programming analysis as "black boxes" with the output of one used as input to the other.[14] Initially an efficient capital budget

[8] The firm is willing, if necessary, to sacrifice all growth in order to maintain *current* dividends. Thus, there is *no* acceptable trade-off between reducing dividends below current levels and increasing final cash. If trade-offs are permissible, payment of dividends at the current level should be included as an activity.

[9] In setting up the capital budgeting problem the firm does not know whether it will be able to allocate $10 or $10,000 for *increased* dividends in year 1, but its preference function is such that if it allocates an extra $10 for year 1 it wants to allocate an extra $20 in year 2 and $30 in year 3. That is, it wants to *increase* dividends at a steady (linear in this case) rate.

[10] If the firm is not in the maximum tax bracket, it may be desirable to incorporate in the analysis a calculation of the taxes the firm should aim to pay in each year. To do this we simply incorporate "Before-tax cash" restraints with transfer activities into the "Tax-free cash" rows. If the first $10,000 pays tax at the rate of 25 percent, the first taxation transfer activity (limited to $10,000) would take $1 from the "End-of-year cash" row and deliver 75 cents into the "Tax-free cash" row for the beginning of the next year.

[11] Additional technical restraints can be added—such as limiting the program to initiating Project 1 in year 1 or year 2 or year 3 and controlling borrowing activities to available amount or debt-equity ratios.

[12] This interface is crucial to the capital budgeting analysis. It is quite conceivable that the future cash flows from the other operations of the firm will influence the current investment decision. For example, if a temporary loss from other operations is projected for next year, cash may be put in the bank to cover that projected loss rather than invested in equipment during the current year.

[13] If we make investment i, if we use financing system j, and if we depreciate according to schedule k, then the cash flows in the first, second, third, etc., years will be.

$$a_{ijk1}, a_{ijk2}, a_{ijk3} \cdots .$$

This is the sense in which the cash flows are described as being "technical." They follow from conscientious application of budgeting procedures.

[14] Other approaches have been suggested to establish the weights for goal functions and checking their internal con-

for a specified set of relative weights of the goal functions would be presented to the decision makers. The decision makers would then be used as a black box to tell us the direction of the relative changes in the weights which they think would lead to an improved solution. If they can not do this directly, parametric programming in the neighborhood of the suggested weights would indicate the rate of substitution between different goal functions; for example, how much increased pollution must be sacrificed to increase the final asset value of the firm. The decision makers could then decide whether a shift in that direction is desirable. If so, new sets of budgets in that direction could be programmed and reexamined in the same way. *In this way we can feel our way towards an optimal capital budget without ever explicitly defining the decision maker's preference function.* The sequential identification of improved capital budgets would be continued until a budget is found that is better than all adjacent budgets or until the rate of gain in the objective function is lower than the per unit cost of further analysis.

The specification of initial weights for the alternative goal functions may be difficult. It should be noted, however, that since we propose a sequential analysis for a problem for which it is assumed that a local optimum is global, the starting point is not really terribly important. We could, for instance, start by maximizing final cash and then increase the weights of those goals which were felt to have outcomes at too low a level in the cash-maximizing capital budget. Some guide to the appropriate weights may be available by quite simple a priori considerations. In the pollution example cited earlier, the air-polluting project was given a score of -100 on the pollution scale. If the decision makers feel that, ceterus paribus, they would be willing to forego this project if it does not add at least \$20,000 to final cash, the implication is that the initial weight for the pollution goal might well be set at \$200 of final cash per unit.[15]

sistency, notably the Churchman-Ackoff Value Measure [2].

Conclusion

This paper has shown that mathematical programming can be used to generate efficient capital budgets for capital budgeting problems involving multiple goals. Iterative confrontation of decision makers with the resulting efficient capital budgets has been suggested to give improved estimates of the relative importance of competing goals. In addition, it has been shown that capital budgeting decisions can be interfaced with the other operations of the firm. The suggested approach is thought to constitute a major break with the independent, one-dimensional analyses used in payback, internal rate of return, or even discounted cash flow procedures of capital budgeting. The internal rate of return is not even implicitly fixed, but rather is discovered (and may vary between time periods) as a result of the iterative redefinition of the decision maker's goal weights.

[15] Ceterus paribus, the effect of introducing the air-polluting project is to *lower* the objective function by 100 λ_3 in Table 1. In the suggested example, the decision makers start by feeling that they would be indifferent to use of this project if it increased final cash by only \$20,000. Hence, for our initial estimate we believe that $\$20{,}000-100\lambda_3=0$ is a break-even value of λ_3; or $\lambda_3=\$200$ is a break-even value of this weight.

Note that this is not \$200 per \$1 of expenditure on pollution, but \$200 of final cash per unit of the arbitrary pollution scale which was established by giving the air-polluting project a score of 100. There is no direct connection between our procedure and information that could be obtained on a cost accounting basis. While the *initial* estimate of the weight to be given to the pollution goal may be \$200 per unit, it may subsequently emerge that, in the light of the other weights used and the production possibilities, the optimum weight may be found to be, say, \$50.

A Note on Fluctuations in Supply and Farmers' Income*

S. ECKSTEIN AND M. SYRQUIN

IN DISCUSSIONS about short-run fluctuations in the supply of agricultural products, it is commonly implied that because of the low elasticity of the demand for such products, fluctuations bring about a deterioration in farmers' average income. Such a statement is misleading and at best incomplete without further information about the shape of the demand function over the relevant range.

The correct conditions for the farmer to benefit from output instability have been stated by several authors [2, 3, 5, 6]. The purpose of this note is to examine the relationship between the shape of the demand function and farmers' income. It will be shown that concavity of the total revenue function is the important concept and not the elasticity of demand. Thus, with linear demand functions, supply fluctuations will cause a decline in farmers' average income, whether price elasticity over the relevant range be greater or smaller than one. In contrast, when the demand function is of the constant elasticity type, average income will increase when elasticity is smaller than unity and decrease when it is greater—quite contrary to common belief.

In part I the main results are formally derived, and in part II an empirical application is presented.

Let us assume a perishable crop, with supply fluctuating around the average quantity $\overline{Q}$ at regular intervals w. The market supply curve is completely inelastic and so the demand curve determines the price and revenue at each period.

Let the demand function be

$$P = f(Q) \tag{1}$$

and let T and M denote total and marginal revenue, respectively, and η the price elasticity of demand defined as $\eta = -(dQ/dP)(P/Q)$.

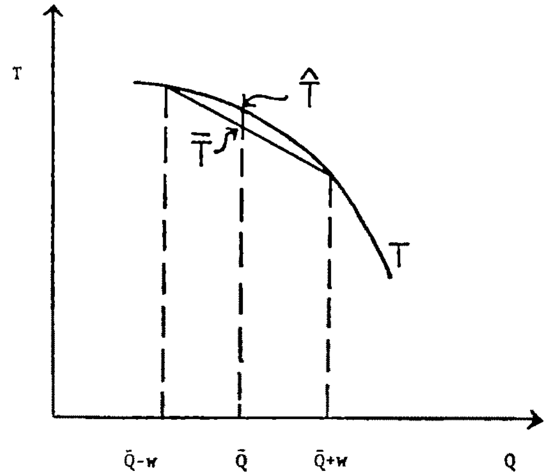

Figure 1

In any particular period i, farmers' total revenue will be

$$T_i = P_iQ_i$$

and average revenue over n periods, which we shall denote by $\overline{T}$, will be

$$\overline{T} = \sum \frac{P_iQ_i}{n}. \tag{2}$$

If crops were supplied to the market in a constant flow, disregarding cost of storage, mean-crop revenue, denoted by $\hat{T}$, would be

$$\hat{T} = f(\overline{Q})\overline{Q} = \overline{PQ} \tag{3}$$

where $\overline{P}$ is the price corresponding on the demand function to $\overline{Q}$.

The higher-crop period will produce a greater revenue for the farmer when $\eta > 1$ and a smaller revenue when $\eta < 1$.

As can be seen from Figure 1,[1] the *mean-crop revenue* ($\hat{T}$) will exceed the *effective mean-revenue* ($\overline{T}$) (i.e., fluctuations will cause a reduction in income) as long as the total revenue curve is concave. This implies that the marginal revenue

* We would like to thank the referees of this Journal for very helpful comments and suggestions. Syrquin's work was supported by the Project for Quantitative Research in Economic Development, Harvard University.

S. ECKSTEIN *is associate professor of economics at Bar Ilan University, Ramat Gan, Israel. M. Syrquin is lecturer in economics at Harvard University.*

[1] We deal here with only two periods for the sake of simplicity. The analysis can be generalized assuming Q_i to be distributed according to a given density function with $\overline{Q}$ as its mean. The analysis would not be changed, but on the empirical part we would have to assume Q_i and e_i (the random error in the demand regressions to be estimated) to be independently distributed.

is downward sloping, as it is usually assumed to be and is invariably so drawn. Assuming now P to be a decreasing monotonic twice differentiable function of Q, we have

$$M = T' = P + P'Q \tag{4}$$

or

$$M = P\left(1 - \frac{1}{\eta}\right) \tag{4'}$$

$$M' = 2P' + P''Q \tag{5}$$

Therefore, if the demand has a negative slope ($P'<0$) fluctuations will reduce average income ($\hat{T} \geq \overline{T}$) if

$$-\frac{P'}{QP''} \leq \frac{1}{2} \tag{6}$$

which is always the case for linear or concave to the origin demand curves[2] ($P' \leqq 0$).

The constant elasticity function is frequently used in empirical demand studies. It is therefore interesting to examine it in the present context, especially since it yields quite unconventional results.

Derivating (4′) with respect to Q with η being constant by assumption, we find

$$M' = P'(1 - 1/\eta) \tag{7}$$

That is,

$$\overline{T} \gtreqless \hat{T} \text{ as } \eta \lesseqgtr 1.$$

The surprising conclusion is that under these demand conditions farmers' revenue will rise as a result of supply fluctuations when price elasticity is *smaller* than unity and fall when it is greater.

II

Let us now illustrate the implications of crop fluctuations in agricultural short-run supply with an empirical example. The data are taken from a recent study of demand functions in the cooperative vegetable wholesale market in Tel Aviv [1] and refer to October–November of 1964.

Daily data of the quantities of grade A tomatoes brought to the market and the prices obtained through auction sales were examined. Three subgrades (A-1, A-2, and A-3, in descending order) were considered, over a time span of seven weeks. Separate functions were estimated for the three subgrades, and dummy variables introduced to take care of the week effects.

Thus we have[3]

$$\ln P_{gij} = a_g \ln Q_{gij} + \sum_{i=1}^{7} W_{gi}D_{gi} + e_{gij} \quad (j = 1, \cdots 5) \text{ for each } g = 1, 2, 3 \tag{8}$$

where

P_{gij} = observed price of grade g in day j of week i;

D_{gi} = dummy variable for week i in the regression for grade g;

e_{gij} = random error of gijth price.

Let us assume that tomatoes could be stored over the week to provide an even daily flow equal to the week's average. (Since there are only five market days, this is a reasonable assumption.) The effective mean revenue for each grade and week would then be equal to

$$\overline{T}_{gi.} = 1/5 \sum_{j=1}^{5} P_{gij}Q_{gij} \quad \text{(for given } g \text{ and } i\text{)} \tag{9}$$

and over the whole period

$$\overline{T}_{g..} = 1/35 \sum_{i=1}^{7} \sum_{i=1}^{5} P_{gij}Q_{gij} \quad \text{(for given } g\text{)} \tag{9'}$$

The weekly mean-crop revenue would be

$$\hat{T}_{gi.} = \hat{P}_{gi.}\overline{Q}_{gi.} \quad \text{(for given } g \text{ and } i\text{)} \tag{10}$$

where $P_{gi.}$ is the price on the estimated demand function corresponding to the mean-crop $\overline{Q}_{gi.}$ and the mean-crop revenue over the whole period

$$\hat{T}_{g..} = 1/7 \sum_{i=1}^{7} \hat{P}_{gi.}\overline{Q}_{gi.} \tag{10'}$$

However, the latter expression cannot be compared outright with (9′) because of the random error e. Rather, it must be compared with what farmers could expect under "normal" market conditions, i.e., prices corresponding on the estimated demand function to the observed daily quantities, eliminating the respective week effect. Let us call this quantity the *esti-*

[2] The expression in equation (6) can be identified as the elasticity of the marginal demand curve (P'). J. Robinson used the same concept in a different context [4] and referred to it as a measure of "the adjusted concavity of the average curve" (p. 40).

[3] The model is specified without an intercept because otherwise the ($X'X$) matrix would become singular in the presence of dummy variables. An alternative procedure is to leave the intercept and delete one of the dummy variables.

mated mean revenue, denote it $\tilde{T}$, so that for each week and grade we have

$$(11) \qquad \tilde{T}_{gi.} = 1/5 \sum_{j=1}^{5} \hat{P}_{gij} Q_{gij} \qquad \text{(for given } g \text{ and } i\text{)}$$

$$(11') \qquad \tilde{T}_{g..} = 1/35 \sum_{i=1}^{7} \sum_{j=1}^{5} \hat{P}_{gij} Q_{gij} \qquad \text{(for given } g\text{)}$$

The results obtained for the whole period, in I. L., are summarized below:

	Symbol	Grade A-1	Grade A-2	Grade A-3
Adjusted price elasticity[4]	η	17.2	7.0	8.6
Effective mean income	$\bar{T}_{g..}$	13,004	18,574	19,322
Estimated mean income	$\tilde{T}_{g..}$	12,990	18,725	19,925
Crop-mean income	$\hat{T}_{g..}$	13,080	19,075	19,995
Ratio $\bar{T}/\hat{T}$		.9942	.9737	.9663
Ratio $\tilde{T}/\hat{T}$		.9931	.9816	.9650

If we assume profits to be 20 percent of revenue, a difference of 4 percent in TR (as for grade A-3) would represent a 20 percent difference in profits, which appears more impressive than the .965 $\tilde{T}/\hat{T}$ ratio.

The $\tilde{T}/\hat{T}$ ratio depends, besides of the value of η, on the variance of the crops around their mean.

The averages (for the seven weeks) of the standard deviations of Q_j around their means for the three different grades of the empirical part are: grade A-1, 3.9; grade A-2, 7.4; grade A-3, 10.5. The large standard deviation for grade A-3 partially explains its relatively low $\tilde{T}/\hat{T}$ ratio.

Finally, whereas for $\eta > 1$ the relative differences are small, they are much greater for $\eta < 1$. These relationships are illustrated in the following table, computed for a simple two-period model with relative fluctuations of 10 percent and 50 percent and price elasticities of 5 and 1/5:

Value of $\tilde{T}/\hat{T}$, in two-period case, for

	$\eta=5$	$\eta=1.5$
$w=0.1$	0.999	1.11
$w=0.5$	0.979	8.10

This explains the low ratios of estimated to crop-mean revenues obtained in the empirical data cited above and the between-grade differences of these ratios that, in turn, depend on the price elasticities and crop fluctuations observed in each case.

Evidently, the empirical value of these results depends on the accuracy of the estimated demand functions, because both the numerator and the denominator of these ratios are computed at estimated daily and weekly price levels, respectively. However, the fact that $\bar{T}/\hat{T}$ does not differ significantly from $\tilde{T}/\hat{T}$ seems to imply that the estimation is acceptable. As was shown in the preceding sections, the sign and magnitude of these ratios depend on the functional model assumed to represent the true market situation.

We pointed out that had we estimated linear demand functions, the outcome—fluctuations causing losses—would have been actually assumed. The constant elasticity model used in the empirical part is free of this charge, and therefore its results as to the negative effects of fluctuations are easier to accept. There is one further question, however, whose answer depends again to a large extent on the functional form assumed. Having found the harmful effects of fluctuations, some sort of mechanism to even out the marketable flow (like cooperative storage) would seem to be justifiable. But what is the maximum that we should be willing to pay for such a service? The answer depends on the magnitude of the $\tilde{T}/\hat{T}$ ratio. For comparative purposes only, we calculate these ratios from a linear-demand model:

Grade	slope (dP/dQ)	η (at $\bar{Q}$, $\bar{P}$)	$\tilde{T}$	$\hat{T}$	$\tilde{T}/\hat{T}$ Linear	$\tilde{T}/\hat{T}$ Double log
A-1	−.6245 (t=1.7)	8.91	13,005	13,305	.9775	.9931
A-2	−.6479 (t=4.8)	4.73	18,574	19,872	.9347	.9816
A-3	−.2177 (t=3.1)	6.90	19,232	20,141	.9594	.9650

[4] In estimating the equations, lnP was used as dependent variable. The "adjusted price elasticity" in the text is therefore the reciprocal of the estimated coefficients. The estimated regression coefficients and their t ratios are:

Grade	$1/\eta$	t
A-1	.058	(1.3)
A-2	.143	(4.6)
A-3	.116	(3.0)

The dummy variables were in all cases significant.

We see that cases could arise, depending on the cost of the storage services, under which econometrician A, having chosen a double log model, would reject the storage program as too costly, while econometrician B would favor it based on his linear demand calculations.

PROGRAM DEVELOPMENT IN THE NATIONAL BUREAU OF ECONOMIC RESEARCH

Recent planning and research activity at the National Bureau of Economic Research involves significant expansion into urban and regional studies, studies of human resources and social institutions, and studies in industrial organization. Programs of research on the structure of the economy and on the social and economic factors contributing to the quality of life and environment are in a broad way the new emphasis in Bureau activity. Questions concerning distribution of income and services within and among groups and economic sectors are now as much an integral part of the Bureau program as are the older or more traditional study areas including economic growth, national income, consumption, capital formation, business cycles, financial institutions and processes, and international economic relations. The new emphasis is on the quality and distribution of the fruits of economic activity as well as on factors determining the magnitude of the aggregate product.

In terms of method, much work continues in the aggregative macroeconomic style that has been characteristic of the Bureau through its first half century. In this 50th anniversary year, however, there is new emphasis on econometrics and measurement methods and on organization of electronic computer services in support of economic research. The Board has approved a "Proposal for the Creation of a Computer Research Utility in Economics and Management Service." This will be available to the relevant academic research community nationwide on a time-shared system operating through consoles.

The Bureau research covers a major part of the national economy. Some of the concepts and methodology have a broad relevance to agricultural economics and especially to that part dealing with economic growth and development of public policy. Colloquia topics in recognition of the 50th anniversary of the Bureau include, for example, The Business Cycle Today, Public Expenditures and Taxation, Finance and Money Markets, Industrial Organization, Human Capital, and Economic Growth. This report cannot offer a comprehensive review and, instead, concentrates mainly on some of the recent developments, particularly those that are believed to be of most interest to agricultural economists.

Urban Studies

Urban studies currently involve (1) a long-range effort to develop simulation models for explaining changes in urban spatial structure and (2) other urban problems such as employment problems in ghetto areas and effects of state tax transfers on local government. A land-use modeling study attempts to obtain improved and more complete econometric estimates of the determinants of location and other aspects (tenure, single family vs. apartment dwelling, and size of unit) of residential and industrial choice. Related to this is an attempt to develop "abstract" models that simulate the land and housing markets. These models are built by representing activities in a market setting involving in the case of housing a supply submodel, a demand allocation submodel, and a market or assignment submodel.

Residential location research attempts to extend and test empirically the basic theoretical framework of the classical residential location model. This is done first by identifying decision variables (income, race, sex of household head, number of employed people in the household, and stage in a family's life cycle or family size). The second step or extension of the theory is to allow decision makers to exercise their choices among locations that differ according to housing quality, land-use patterns, public services, social amenities, and the degree to which transportation links the various locations to each other and to places of employment. Another project in household location involves residential choices over time in terms of decision to move, tenure choice (ownership or rental), choice of neighborhoods, and housing characteristics.

Research on determinants of industrial location within metropolitan areas seeks to determine those

factors that are most important in the intrametropolitan location decisions of manufacturing establishments and then to use the quantitative information in these factors in construction of a prediction model of future locations. The research design centers attention on the importance of marginal components such as new firms, firms relocating within the area, firms going out of business or moving out of the area, and firms expanding their employment at present locations. Source information from the Dun and Bradstreet Corporation is being used in part of this reasearch. Data are available on an establishment basis, giving the following: specific location; year of formation; number of persons employed in the establishment and in the entire firm; codes indicating whether the location is a headquarters, branch, or subsidiary in a multibranch or multifirm corporation; and codes indicating classification of the establishment in terms of products produced, if any. The ultimate goal is not only to understand the dimensions of the location process but to determine which factors most strongly influence the intrametropolitan location decision and to quantify those decisions using behavioral models.

Research on ghetto employment problems is an example of the more recent attempts in the Bureau to undertake analysis of specific socially significant problem situations. This research as well as that on manpower policy generally rests quite directly on conventional marginal analysis. This takes history and current social institutions for granted and postulates the kinds of marginal adjustments an individual takes to function within the nexus of prevailing institutions. Two approaches are being compared. The "disadvantage" of the person in the ghetto is presumed to vary as the sum of a collection of individual "handicaps," such as relatively little education, lack of specific job or vocational training, or little information about job opportunities. Then presumably any marginal improvement of any relevant labor market characteristic will bring about an incremental improvement in the worker's labor market situation.

An alternative approach, on which emphasis is increasing, presumes that ghetto employment problems are an outgrowth of the prevailing institutions, that class distinctions and other retarding or differentiating situations among employees are maintained and manipulated in such a way as to maximize the advantage of those in control of the institutions. If this presumption is correct, it would lead to the general conclusion that labor market outcomes are determined primarily by those characteristics along which class distinctions are made and only secondarily by those characteristics to which economists conventionally attribute productivity. The research attempts to compare alternative sets of variables influencing labor market outcomes such as education and job experience, which are presumed to be related to productivity, with variables like race and sex, which are presumed to be more distantly related. Quantitative tests for discontinuities in the labor market are being attempted to determine if there is really a "secondary" labor market. The empirically derived definition of the secondary labor market may be used to help explain the effectiveness of the variables in influencing wages, occupational status, and other labor market outcomes. The results of this research can have important policy implications.

Regional Economic Studies

Differences among regions in economic and social conditions are the basis for various cross-sectional studies that are aimed at understanding these differences and their policy implications. Recent studies include differentials in hourly earnings in the United States, interregional migration flows, regional unemployment, and regional specialization in wheat production. Generally the attempt is to develop general conclusions and models of economic behavior. Although these studies are not a large part of the Bureau research, they may be of particular interest to agricultural economists because of the inferences for policy and because of our increasing involvement in community, rural, and human resource development.

Conflicting views concerning magnitudes of wage and income differentials among regions and the reasons for them are at the center of many controversies regarding the performance and equity of the economic system. Reduction of such differentials has been the stated purpose of many laws at federal, state, and local levels in recent years. Research in this area appropriately concentrates, therefore, on identifying the breadth and magnitude of such differentials and relates these to factors believed to be associated with them.

Current study on regional and city-size wage differentials has the following control variables: color, age, sex, education, occupation, and industry (classified by extent of unionization). It covers all nonfarm employed persons, including salaried and self-employed, and all nonfarm industries and occupations. Objectives include attempts to determine how large the differentials are after allowing for differences in city size, education, and other variables; to determine the interaction among such variables (for instance, is city size more important for whites or blacks, for females or males, etc.); and to provide a baseline against which differentials can be measured. The basic source of data is the one-in-a-thousand sample of the 1960 Census of Population. When data from the 1970 Census become available, tests may be run relating to the impact of the civil rights, education, and other legislation of the 1960's.

Studies of wage and income differentials, combined with other studies such as interregional migration flows, regional unemployment, and the like, offer suggestions for organizing research with which agricultural economists may be engaged in community and rural resource development. Wage and income

differentials among regions, areas, or communities, identified according to selected control variables, give a measure of under- and over-allocation of human resources in respect to other resources of a community, area, or region. Since moving or migration and other adjustments involve a cost, such data are one of the factors to be taken into account in development programs.

Human Resources and Social Institutions

One of the most significant expansions in the program of the Bureau is the new research on human resources and social institutions. Primary emphasis has been placed on developing a framework for human capital analysis under three separable program areas: (1) the relation between human capital and personal distribution of income in terms of the influence of schooling and post-schooling investment on the structure and time profile of earnings; (2) influence of human capital on consumption and labor-supply decisions; and (3) the influence of economic incentives on greater participation in illegal activities under the hypothesis that the frequency or type of illegal (criminal) behavior is responsive to relative gains and costs as visualized by potential participants.

During the past year, the Bureau has begun another series of studies on selected aspects of the relation between the stock of human capital, as reflected by educational attainment, and economic or social behavior. One set of studies deals with the influence of educational attainment on specific types of behavior which have measurable although not necessarily direct economic consequences. Another group of studies analyzes the economic returns to education, especially to higher education, corrected for the relation between "ability" and earnings. A number of different samples are being used to examine the relation between ability, education, and earnings. A model is being developed to explain changes in the stock of human capital over time, with particular emphasis on the role played by depreciation and post-schooling investment.

An interregional analysis of income distribution investigates the effect of human capital on the inequality and skewness of income or earnings. Findings of cross-sectional analyses for the United States, Canada, and the Netherlands, with comparisons among the United States, Canada, Puerto Rico, Mexico, Israel, and Great Britain, indicate (1) that schooling can explain a considerable proportion (often 15 to 20 percent) of the variation in income within a region; (2) that across areas either the rate of return or schooling inequality or both are positively correlated with the inequality of income; and (3) that there does not appear to be any systematic relation between the rate of return and the inequality of schooling.

A study on consumption, working time, and age is designed to explain how consumption varies with age to uncover the determinants of life cycle consumption patterns. The model emphasizes the dependence between life cycle consumption and life cycle labor-supply decisions. The demand for market goods varies with age. Variations in the price of time with age affect consumption in two ways: (1) A rise in the wage rate is a rise in the price of consumption time relative to market goods. When the wage rate is rising with age, individuals tend over time to substitute market goods for consumption time in their nonmarket production. (2) A rise in the wage rate implies a rise in the "shadow" price of household commodities. Changes in the derived demand for market goods depend, therefore, on changes in the wage rate with age.

The role of firms as suppliers of human capital assumes that firms are engaged in joint production, with human capital output as a by-product of production of market goods. Firms produce goods and services to sell, and they also produce human capital which is sometimes sold to employees. The cost of production is the foregone output necessary to produce the human capital, which appears in the form of increased knowledge about production processes and learning by experience, as well as outright training services such as those received by apprentices.

Some human capital has market value, and this can be sold to employees in the form of wage payments below opportunity costs as employees accumulate capital. Age-investment profiles and depreciation or obsolescence age-earnings profiles have implications for job training or other educational programs.

Some investments in human capital are entirely specific to the firm and have no alternative uses outside the firm. The problem in this case is to determine the firm's optimal accumulation of such capital. Specific capital output may take the form of additions to knowledge that shift the investing firm's production function without changing the production functions for other firms. Rational allocation of resources in time produces what appears to be secular improvements in total factor productivity that otherwise would be attributable to technical change or increasing returns to scale.

Studies in Industrial Organization

Studies in industrial organization involve four major areas: (1) the service industries, (2) economics of health, (3) diversification of industry, and (4) managerial incomes and stockholder returns.

The project on the service industries was begun in 1963 with the financial assistance of the Ford Foundation. A recent summary volume, *The Service Economy* [2], traces the transition of the United States from an industrial to a service economy and explains the growth of service employment, primarily in terms of developing a slow increase in output per man in the service sector. The service sector is compared with industry with respect to such factors as hourly earnings, behavior over the business cycle, industrial organization, and labor force char-

acteristics. Other publications deal with production and productivity and other aspects of the service economy.

Studies in economics of health, supported by grants from the Commonwealth Fund and the National Center for Health Service Research and Development, are designed to gain a better understanding of the factors affecting the demand for health and medical care, the productivity of medical care, and the socioeconomic determinants of health. A model of the demand for health assumes that consumers inherit an initial stock of health which depreciates over time and can be increased by gross investment. Gross investments in the stock of health are produced by medical care, a person's own time, diet, exercise, recreation, and other factors. Health is a consumption commodity directly affecting peoples' preference functions. Good health is a value in itself, sick days are a source of disutility, etc. Health is also an investment commodity determining the total amount of time available for market and nonmarket activities. Demand for health is a function of wealth, its relative "shadow price," and a monetary internal rate of return to an investment in health. Empirically, the study employes multiple regression analysis to estimate demand curves for health and derived demand curves for medical care. Whether health is measured by length of life or by healthy days, education has a positive and significant regression coefficient in the health-demand curve. An increase in age simultaneously reduces health and increases medical expenditures. A suggested continuous compounded rate of growth of the depreciation rate is 2.0 percent per year over the life cycle. The elasticity of substitution between present and future health is small but positive.

The study of the socioeconomic determinants of hospital use examines how extra-medical conditions of a hospitalized patient and institutional characteristics of the hospital where he is treated affect the amount and type of services the patient receives.

A study of the economics of accidents is built on formal model that identifies the factors affecting the incentives to invest resources in accident prevention or safety. It is hoped that this study will shed light on the current controversy in the automobile accident field between proponents of the fault system and advocates of replacing the system with self-insurance that approximates one of absolute liability.

Problems of Measurement

New attempts are underway to provide more satisfactory measurements of economic and social performance.[1] The existing income and product accounts, such as "Gross National Product" and the National Income Accounts, measure economic activity in the market, supplemented by imputed measurement of a few closely related nonmarket activities. At present and historically, however, a great deal is omitted that has to do with measurement of real income and investment. The accounts include as assets, for example, only tangible business assets and housing. These omissions become increasingly serious as emphasis is increased on studies of the structure of society and the performance of factors contributing to the quality of life and environment.

The current dissatisfaction with GNP accounts relates to specific areas: (1) the treatment or omission of nonmarket activities; (2) the way in which output is classified between consumption and investment; (3) the widespread use of input costs to measure the magnitude or value of output; and (4) the adequacy, or rather the inadequacy, of the accounts to measure output in terms of social and economic welfare. The problems of measurement relate to questions both of what is to be measured and of what analytical purposes are to be served.

In general terms, economic and social output is conceived as a flow of satisfaction or utilities derived from various combinations of capital assets, plus or minus changes in the value of the assets themselves. A suggested classification for the assets to be included has been presented [2, p. 14]: (1) tangible capital assets (equipment and structure); (2) intangible capital assets (knowledge); (3) human capital assets (skills and talents); (4) physical environmental assets; (5) sociopolitical environmental assets. Tangible assets include business assets, consumer assets divided into housing and durable, and government assets. Intangible assets are human capital and other resources applied to research and development which result in socially useful knowledge that is analytically distinct from the skills and talents of people who produced it. Human skills and talents include both innate ability and training. Physical environmental assets are natural resources, as traditionally viewed, plus results of man's development efforts (parks, forests, flood-control facilities, etc.) minus depreciation or deterioration. Assets in the sociopolitical category are meant to include such concepts as equity, security, freedom, social and economic mobility, privacy, and so on.

Although many problems are involved in this (or any other) classification, the argument is made that its use would result (1) in recognition of a much wider range of outputs as contributing to economic and social welfare and (2) in explicit recognition of changes in stocks over a wide range, thus giving more meaning to measures of net output since output partly consists of changes in stocks. Items to be brought into the accounts are large. Business firm expenditure on research and development, which would be added to gross investment, have been exceeding $20 billion a year. The total value of the stock of human skills and talents in aggregate probably would be much larger than stocks of business

[1] See especially, F. Thomas Juster, "On the Measurement of Economic and Social Performance," in [3, pp. 8–24]; see also [1] and [7].

capital. The consumer and government assets in the form of roads, parks, dams, appliances, furniture, etc., are also much larger than business-owned capital assets. Natural and environmental resources are of growing importance in our concerns for the quality of life. They are important in any measure of national wealth or gross national product; and more accurate measurement of resource appreciation, depletion, or despoliation is essential for guiding programs of production or investment in natural and environmental resources.

Implications for Agricultural Economics

Some of these dissatisfactions with current accounts and the problems involved in improving the measurements have peculiar implications for agricultural economists. These relate not only to traditional problems involved in attempting to measure income in agriculture and, to a lesser extent, factor productivity, but to broader problems now inherent in involvement in programs of community and human resource development. It is not clear, for example, where emphasis should be placed in program development between human and natural resources or between a labor-surplus low-income area versus one higher up in the income and product scale. More satisfactory measures of progress or improvement in welfare that we can apply to the local community are urgently needed. The problem of measurement is one requiring more comprehensive and theoretically meaningful treatment as a guide for more effective program development. Agricultural economists should welcome the attempts in National Bureau research to broaden and sharpen the measurement of income and product accounts, and it is hoped that ways may be found for contributing to the effort.

In a more positive view, other more specific conclusions may be drawn in regard to the trends in National Bureau research: (1) The new emphasis in regional economic studies in urban areas may help to identify a framework for working in community and human resource development programs in the nonmetropolitan sector. (2) The new emphasis in human resources and social institutions suggests ways of studying the effectiveness of education and other institutions or programs designed to improve the human resource. (3) The studies in industrial organization, especially those dealing with the service industries, suggest research for improving the environmental services of the nonmetropolitan community. Research by agricultural economists and rural sociologists on development of improved medical facilities and services in nonmetropolitan areas now has a counterpart in the work on economics of health and health services. An interaction may be beneficial. (5) The Bureau emphasis on regional research and the service industries suggests a framework for research in intraregional and interregional differences in farm income and in various aspects of farm-nonfarm mobility, employment, and earnings.

As the work and career agenda of agricultural economists expand to include the total nonmetropolitan economy, including farm and nonfarm economies, the relation of these economies to the national economy becomes increasingly significant. The new challenge to agricultural economists is (1) to a broadening of their research outlook and (2) to a more empirically accurate research output in a general macroeconomic as well as microeconomic context.

MICHIGAN STATE'S KELLOGG FARMERS STUDY PROGRAM: A PROGRESS REPORT

It is generally true that rural people are not adequately prepared to participate effectively in public affairs. In general, the rural population does not have easy access to schools that offer high-quality courses in social studies, government, economics, speech, composition. literature, and history. Today more rural people are acquiring some college-level education in community colleges, short-course programs, or regular university curricula. While these experiences may be broadening, they often deal almost entirely with technical subjects.

Recognizing this shortcoming among young Michi-

gan farm businessmen, Michigan State University and the Cooperative Extension Service, with the financial aid of the W. K. Kellogg Foundation, developed a continuing adult education program. This program, the Kellogg Farmers Study Program, has been in operation since 1965 on an experimental basis. The rationale for the Michigan State project was the demonstrated fact that successful Michigan farmers with sound management talent, utilizing the latest in scientific and technical know-how, were lacking in the liberal arts and social science knowledge and understanding necessary to effective participation in today's complex urbanized and industrialized society. The stated objectives of this experimental program have been:

(1) to provide an understanding of the social, economic, and political framework within which modern agriculture functions as an integral part of an urbanized industrial society;

(2) to use this framework in analyzing state, national, and international problems, both agricultural and nonagricultural; and

(3) to develop the creativity and analytical ability of the individual; to broaden his cultural and social perspective; and to provide him with tools and experience in the art of communications so that he may assume more effective and responsible roles of leadership and informed followership in the many "communities" in which he is a citizen.

To accomplish these objectives, groups of 30 farmers have been chosen each fall since 1965 to participate in a three-year program. Selection for the program is through nomination and application and has been based on four criteria: (1) commitment to agriculture as a means of livelihood; (2) membership in the 25–35 year age group; (3) possession of potential leadership ability; and (4) a demonstrated interest in public and community affairs. From the beginning, selection as a Kellogg Farmer has been a prestigious event for participants and their communities.

The program format includes nine weeks of study institutes on the MSU campus; three two-day summer institutes with wives participating; and state, national, and international traveling seminars. The campus-based institutes have provided approximately 370 hours of classroom instruction. University, government, and industry representatives have covered a broad array of subject matter areas, including political science, economics, sociology, communications, education, history, philosophy, and the arts. Wives of the participants are formally involved in several aspects of the program.

The accompanying curriculum is an example of the hours devoted to each general topic and of the year-to-year transitional development. During the State Traveling Seminar, participants spend a day with their state legislators discussing issues of mutual interest and observing a legislator's typical day's duties. The participants also meet with representatives of the various departments in the executive branch of state government, with representatives from the judicial branch, and with lobbyists to gain an understanding of their functions. Another part of the State Traveling Seminar is a trip to inner-city Detroit to talk with low-income people and to observe various social institutions operating to effect change. At the end of the second year, a two-week National Traveling Seminar takes participants to Washington, D. C., where they meet with officials in the USDA and HEW. They meet with Supreme Court judges, their congressmen, and lobbyist groups. They also travel to southern and western states to observe social institutions operating in both urban and rural settings and different kinds of agriculture.

The third year of the program is devoted to preparation for a four–five week International Traveling Seminar. This involves examining the geography, religions, history, social, political, and economic systems of these countries, as well as U. S. foreign policy and foreign policy of other countries.

During the campus-based institutes, participants meet informally with university professors, industry representatives, and government officials, with whom they discuss freely many problems, issues, and ideas. They also attend concerts, plays, and other fine arts performances scheduled at the university.

At the end of the five years of program operation, the dropout rate has been minimal. Of the 90 farmers starting in Groups I, II, and III, 85 completed the three-year program. Groups IV and V are presently intact, with their full complement of 30 farmers each. The attendance rate at institutes and travel seminars has been extremely high. Group I participants contributed their time away from home and travel expenses to the campus institutes. Each successive group has contributed more toward the program budget. Group IV is paying $150 per year tuition and, in addition, will pay about 60 percent of the cost of the national and international travel. Group V, selected in the fall of 1969, pays $400 per year tuition and will also share in the cost of the international travel. It appears that participants will make considerable personal sacrifice to take part in this type of adult education program.

We have many individual incidents and impressions from which generalizations concerning success can be drawn. An increase in the level of oral communication skills is strongly in evidence as the program progresses. At least one participant in each group during the first practice session in the communications block chokes up and cannot utter a sound. With patience and encouragement from other participants one such person was rated later by his communications instructor as one of the best speakers of the session. After spending a day in the Detroit ghetto, one Kellogg Farmer commented retrospectively, "That's the first time I ever shook hands with a Negro." Another participant subse-

quently was moved to take his wife and family and some neighbors on his own tour of the ghetto. Five of the 20-member Farm Bureau State Resolutions Committee are Kellogg Farmers. They are among the youngest members of that board and have been influential in the State Farm Bureau's stand on several policy issues as exhibited by last year's resolution on farm labor:

> We are encouraged by the current arousing of social conscience and public awareness with regard to special problems related to seasonal farm workers. . . Even with the recent gains farm employers have provided for seasonal employees there are still problems inherent in migrating from state to state each year, particularly for a group with a low general educational level and when a language barrier is sometimes present. In light of these facts: (1) We commend leaders in government and civic organizations for realizing the presence of these special problems. (2) We encourage members of the legislature and leaders in agencies of government to be informed of the true agricultural labor situation so that understanding, reason, and knowledge of the farm labor system and the agricultural situation will guide the development of legislation and implementation of programs dealing with farming and farm labor. (3) We caution these leaders against reactionary approaches to emotion-packed allegations by certain pressure groups that would lead to the establishment of costly and unwise programs that would be of little value to seasonal farm workers while causing unnecessary hardships on farm families. (4) We encourage state and federal regulatory agencies to work toward simplified interstate recruitment procedures so that workers will be encouraged to have employment arranged before they leave their home states.[1]

Participants have also exhibited a propensity to include in their leadership activities a more political orientation in the local community, state, and international affairs. This year a Kellogg Farmer was elected to the state legislature.

Finally, one Kellogg Farmer decided, after his exposure in the program, to continue his formal education beyond high school. So, in addition to his full-time farming occupation and his participation in the Kellogg program, he is enrolled in the degree program at a nearby community college.

An MSU political scientist, after a block of Kellogg seminars, reported his experience to the faculty and graduate students of his department. His major point was that the academic snobbery exhibited by some of his colleagues in their feeling that only the academician is well-informed and can interpret current events and issues was totally false, based upon his contact with the Kellogg Farmers. He also made the plea that his colleagues should seek out opportunities for similar types of experiences in order that they might better understand and appreciate the level of sophistication people in the "real world" have concerning issues and events of the modern world.

Another MSU professor, much in demand as a speaker, indicated he was drastically cutting his public appearance schedule but that he would always be available to seminars with Kellogg Farmer groups, since they were interested and interesting and were able to present a challenge to him and his ideas during the interchange. He recently asked that the modest honorarium offered him by the program be donated to one of the groups for the continuation of their program after the formal three years were ended.

One group, during the National Traveling Seminar, visited a medium-sized rural town in the South. They spent a day and an evening discussing problems of race, school integration, poverty, employment, and public services faced by the town. They talked with concerned citizens, the students, the poor, and the old line, powerful, white establishment group. Their presence contributed to a better understanding among the citizens of the town, as evidenced by the following except from a letter written to the Kellogg Program staff by one of the town's citizens who helped arrange for the visit.

> You cannot imagine the glowing comments I have received about your farmers from all people in **** and here in ****. They all felt it was such an exceptional group of young men. . . Also, you cannot imagine how much good you all did in all areas; for example, in the case of Mrs. ****, her own boss and coworkers had never really seen her as we saw her that night. Because of this she has been invited to participate in district meetings and has been given much more recognition.
>
> In the case of the families visited, many of these and the leaders were made aware of needs and resources that could be tapped in the community, and they have also been helped.

Finally, each Kellogg Farmer group as it has completed the formal three years of the program has decided to meet at least twice a year for a substantive program to remain current on issues and subjects. They plan their own programs and pay the full costs of their meetings. One such program recently included sessions with the Democratic majority leader in the Michigan Senate for a review of current and pending legislation. Also, they held a seminar with a prominent Michigan civil rights leader. Thus, we can conclude that the program has stimulated an interest in current issues and a desire on the part of participants for continued renewal and updating in public affairs. In addition, recognized agricultural and political leaders in Michigan have indicated favorable appraisal of the program because of the increased participation and sense of mature responsibility they find in the program participants.

The MSU Department of Agricultural Economics

[1] 1970 Policies, Michigan Farm Bureau, adopted by the Board of Delegates of the Michigan Farm Bureau 50th Annual Meeting, East Lansing, Nov. 1969.

and Cooperative Extension Service have become committed to a continuing leadership development effort through the successful application of the experimental Kellogg Farmers Study Program. Accordingly, support for an expanded adult education program in public decision making on a continuing basis is being provided. During the next two years the experiment is being expanded in terms of program levels and intensity, number and types of participants. The campus-based program will be retained as a two-year effort; the very costly internationally-focused third year will be discontinued. Less intensive regional three-year programs are being developed throughout the state. They are focused on local and state public decision making and leadership development. This effort involves more people and will provide a reserve of interested persons from whom participants for the more intense campus-based program can be selected.

Appendix. Kellogg Farmer Curriculum

There is no fixed curriculum for the Kellogg program, although each class studies essentially the same subjects in corresponding phases of the course. The following schedule is typical of the study program. In addition to these courses there are about 100 hours of summer and special institutes, special problems, and outside reading assignments.

First Year	*Hours*
Elements of the pricing system	7
Banking and the Federal Reserve System	7
State and local government	12
American government	5½
Reading more effectively	5
Individual and group communications	22
America as a mass society	5
Problems of the inner city	4
Poverty and its implications	5½
Prospects of farm organizations	1
Ethics and morality in society	6
Natural resources	9
Understanding ballet	1½
National Ballet of Canada—MSU auditorium	2
Second Year	*Hours*
Labor, structure and characteristics	8
U.S. money and fiscal policies	4½
Sources and uses of agricultural data	2
Michigan property taxes—reform or repeal	2
Case studies: milk and cherry marketing	4
Marketing cost studies	15
U.S. Agricultural policy	5
Decision making for producer organizations	3
The Federal executive branch	5
Comparative political systems	5
Attitudes and values in society	5
Large group communications	14
Cultural expressions in art	2
The challenge of world hunger	3
Visits with leaders of farm organizations	10
A geographer's commentary on America	5
Third Year	*Hours*
Trade and economic development	6½
The European Economic Community	10
U.S. and European foreign policies	6½
The language problem	3
World religions	10½
Organizing an effective meeting	1½
Communism as a religious force	1½
Orientation on Europe including farm organizations	6½
Orientation on South America, Asia and Africa	20½
Federal farm programs and history	3
Taking pictures	1
Sensitivity training	3½
Shakespearean theatre	2
"Romeo and Juliet"—MSU auditorium	2

REORGANIZING SOCIAL SCIENCE RESEARCH IN AGRICULTURE*

For a number of years there have been low-key rumblings about the kind of research being done and its potential applicability and suitability both for the short and long run. In recent years these rumblings have become more ominous and widespread among the lay public as well as among professionals [1, 2]. Society is no longer willing to wait for the traditional slow pace of research to find answers to social problems.

Although questions are being raised about the relevance and quantity of research in all sciences, the remarks in this paper will be confined largely to the social sciences as supported by funding through the agricultural colleges; that is, primarily agricultural economics, rural sociology, rural community development, economics of environmental control, and development of natural and human resources in rural areas. However, some of the alternate recommendations given here could be transferred to public-supported research related to other scientific disciplines.

Clearly, we need some sort of aggregate utility function that can be read with precision. Priorities and a relative allocation of resources could be determined by such a function. Priority rankings might persist with changes in resource levels available for research. However, the relative magnitude of research funds and relative number of research man-years allocated to different priorities might change substantially at different total levels of resource availability.

* The author was stimulated to prepare this paper by Carroll Bottum. He also appreciates the helpful comments by Harold F. Breimyer, R. James Hildreth, and others.

Approaches to Research

Let us look at current approaches to research in academic agricultural social sciences. Little inter-researcher coordination or interdisciplinary coordination are employed. Much research work is conceived and carried out by the individual (in association with clerk typists, graduate students, other assistants, and computers) and then individually reported to an anonymous audience—often with little or no reaction expected. Frequently, as far as the researcher knows, this is the extent to which his research is used. Researchers seldom give seminars or workshops based on their research results to *potential users*.

Most researchers at educational institutions write for the edification of their professional colleagues rather than to a wider audience who might make greater use of their research. The university system tends to demand and reward this kind of performance. Apparently publication in the popular press, which has the greatest circulation, is rated the lowest; while publication in the select professional journals, which have a small circulation, is rated the highest. Also, articles written by a single author have a higher rating than those written by several persons. Thus, the kind of individual research that can be deciphered only by the researcher's more sophisticated peers is usually ranked the highest.

In normal life conception cannot take place in a sterile environment. Yet researchers often seem to conceive research problems within the "isolated cocoon" of the educational institution (the ivory tower, if you will), with little or no consultation involving Extension people or others who might have some feel for real-world problems and priorities.

Few project proposals are turned down, although they may be returned for rewording or "reorientation." The researcher complies, and the project is approved in due time. The researcher then proceeds to work on his problem in the way he planned and at his own pace. The work, individually conceived and produced, has little or no supervision because supervision would be considered an encroachment on academic freedom and also insulting by the "eminently well-qualified" researcher.

We have all come to accept this modus operandi, philosophizing that significant discoveries were made on projects only remotely related to the project's objective. Besides, creating a prescription for great minds to follow toward discovery is impossible, isn't it? Some assume that research guidance by the "invisible hand" is sufficient [3].

The time schedule for a typical research project might be as follows: submission of proposal, 30 days; proposal review through all channels, 60 days; normal revisions 30 days; resubmission and approval, 90 days; research development, 90 days; gathering data, 180 days; computer analysis of data 180 days; overall analysis of results, 180 days; writing a research paper, 30 days; journal review, 90 days; normal revisions, 30 days; final acceptance for publication, 60 days; time lag between acceptance and publication, 180 days. This is a total of 1,230 days from submission to publication, or about three and one-half years. Additional time usually elapses before a potential user discovers the journal article or before it is presented in form for potential users. By this time, assuming that the research initially involved an important problem, it may have already been solved some other way.

Other factors are involved in the lag between initiating research and the emergence of findings. Most research workers are not exclusively engaged in research, nor do they work on only one project. They also teach, serve on committees, consult, and advise students. Contrary to a popular misconception among graduate students that a major professor is a leech on the student's creativity and productivity, most researchers could accomplish more research with assistantship money allocated to good clerical-typists.

The academic community has yet to recognize a basic economic principle—that there are economies in the division of labor. The main counterargument is that research and student education are at least complementary, if not symbiotic. Graduate students must be trained. Their research work is an apprenticeship, a kind of on-the-job training; and any research production from them is a positive product. Another argument often made is that researchers (usually part-time researchers, part-time teachers) are better teachers because they use their research to bring important developments to students. There would be a time lag for students of several years if teachers depended entirely upon textbooks and published research.

Although the picture of research in our large educational institutions may not be this dismal, a devil's advocate could project an even worse picture. Much of this research inefficiency and lack of specific problem orientation based on social priorities grows out of the existing organization for research.

Alternate Ways of Organizing Research

Research could be organized and stimulated in several different ways [4]:

(1) *Reorganizing regional research.* The directors the experiment stations in the North Central area have responded to social judgments about the relevance of current research by eliminating the host of regional committees relating mainly to commercial agriculture. Three committees—one on commercial agriculture, a second on natural resource development, and a third on community and human resource development—are the new structure. I believe this restructuring, with only one committee oriented to commercial agriculture, is an attempt at the regional level to reallocate resources or at least to recognize the direction that the Congress (with the power of the purse) wants to go.

However, most of the research funds in land-grant colleges are not in regional research. Most of the money still goes to individual scientists who are not sensitive to a reorientation of priorities.

(2) *Centers of excellence.* The experiment station directors of the North Central region recently proposed another alternative for the organization of regional research, that of establishing "centers of excellence" for specific problem areas.[1] Under this plan, an experiment station would have the broad responsibility for developing and supervising all regional research under its designated "umbrella" program area. Another land-grant university desiring to work in this area would have to look to the designated "center of excellence" for direction and approval of proposed research work. If approved and implemented, this reorganization of regional research could provide the infrastructure needed for better coordination and control and should give stimulus and direction. The directors recommended Nebraska as the program center for Foods and Human Nutrition; Illinois, for Environmental Effects on Crop Production; and Minnesota, for Natural Resource Development, Management, and Use. Other program-center designations would likely follow approval of these recommendations. Although this change in structure would apply only to regional research, such centers could encompass most research funding.

Drawbacks to this plan include difficulties in shifting program emphasis with changes in demand for research in various topic areas. Unless very broadly conceived so that programs could be shifted as priorities change, such centers might be inflexible, because administrative structures tend to persist long after their usefulness is past. And such a structure could also stifle the development of a program at a university that is not the "center," even when the "non-center" university might in fact have substantial competence in that problem area.

Let us assume, for example, that the University of Missouri becomes the center for Community and Human Resource Development. Many of the better researchers in the region interested in that area would gravitate toward the University of Missouri. Graduate students interested in this topic area would likely go there to work on their final degrees. Other professors working in this area, but not on the Missouri staff, might go there during sabbatical leaves. Most of the research done at Missouri on community development should be generally applicable to the entire North Central region.

If a particular state wants to do additional research, perhaps locally oriented, this could be handled in one of several ways:

[1] As initially, proposed, the "centers of excellence" idea was turned down by the Committee of Nine in Washington. However, the President's current budget contains a proposal for a center for community and human resource development in each of the five administrative regions.

(1) Their own research worker or team might go to Missouri for a short period—say, 6 months—to carry out the desired research where the library and expert research counseling in this problem area would be readily available. Also, by physically going to the "center of excellence," the local state researcher would be away from his peripheral committee and teaching duties and could concentrate on the required research work.

(2) The state could contract with the center of excellence for specific research.

(3) The state might pay a researcher from the center of excellence to come there for a specific project.

When statewide extension work in community development is to be initiated, the state could send its Extension team to Missouri for a concentrated short course of perhaps 30 days on a specific phase.

(3) *Contracting with the experiment station for research.* A third method of organizing research would be by contract. This might have less effect on the present administrative structure. Suppose, for example, that 60 percent of all research funds is allocated to the Cooperative Extension Service instead of the experiment station, but with the proviso that this money be used to contract for the research needed to solve the problems confronted. (I suggest 60 percent in keeping with the customary land-grant philosophy of having a majority of research oriented toward practical problems and service work. The remaining 40 percent might be retained by the experiment station for basic research.)

Let the state extension service articulate the specific research demand, allocating the funds according to its estimate of priorities and contracting for the problem-oriented research with its own university research staff. If other universities, such as the centers of excellence, have greater expertise in the problem area, a limited proportion of the funds might be used to contract with these centers.

(4) *Contracting with private research groups.* A fourth method of mobilizing research while applying the division of labor would be to contract with research institutes or corporate research divisions. Doing this would allow universities to concentrate their efforts again on teaching—their historical prime mission. A research-education relationship could be maintained by making arrangements for graduate students to do their research apprenticeships in the research institutes. Also, university teachers might take their sabbatical leaves at one of the research institutes. University staff members who prefer research work to teaching could seek employment with research institutes, government agencies, or in the private sector. However, joint appointments between a research institute and a university would be self-defeating.

(5) *Joint extension-experiment station appointments.* The fifth alternative for generating and carrying out research, one which might disturb present

organizational structure the least, would be to encourage more joint appointments between extension and research, rather than teaching and research or research alone [5]. The assumption here is that the extension worker is better able to recognize the problem areas that need research, to discern the needs that have higher priority, and to allocate his own research time accordingly. On a 50–50 appointment, his time might be utilized best by spending half a year on full-time extension and half a year on full-time research, rather than being half-time in each role the year around. Also, he might be assigned graduate research assistants.

Describing the Demand and Supplying the Product

In almost no other activity has the demand for the service been so frequently generated by the producer as in research. Surely the individual research worker, as a producer, should not be the one to specify the demand for research.

In the last three alternatives for mobilizing research, the setting of priorities, the general orientation, and the decision about the amount of research effort would be taken out of the hands of the individual research worker and would place those research-demand criteria closer to the hands of the ultimate consumer by putting the decision in the hands of the extension service.

Time schedules for research are also an essential part of the demand. Deadlines should be specified for exchange and critique of proposals by each of the researchers involved. Similar deadlines should be specified for the beginning and end of different phases of the research, preparation, and review of results, and their dissemination. On each deadline date the research group might meet in conference or have a conference telephone call, if they are located at different stations, to check on progress, to change orientation where needed, and to reinforce each other's continued interest in meeting specified project goals. After results have been analyzed and reported, researchers should still be responsible for interpreting results, if needed, to extension workers. On some routine basis researchers should also communicate the insights gained and additional findings not usually published. After the research is completed researchers should participate in or conduct training workshops for extension workers when such training is needed.

Since publication credit is important to researchers in terms of salary and promotion, definite arrangements should be made at the outset to publish the results, either in joint publications at varying stages during the whole research program or as a series of seminar or conference papers. Certainly a clear understanding between the cooperating researchers about proprietary rights in a publication is needed at the beginning, so that current and follow-up research and communication to others are not jeopardized.

Other avenues for stimulating and organizing research also need to be explored. It seems feasible to have contract research sponsored by users or groups of users themselves or to have cooperative research that a user group helps to support when the research is of high priority for society and will be made available to all of society. Contract research probably comes closer to having a specified demand for researchers than any kind of research except direct consulting.

If our discipline is to continue making positive contributions to society, these problems need solutions. Some solutions have been suggested here; still others may be needed. But after laying out the avenues of possible change, there is some urgency about making decisions on which avenue to take. A decision made now with imperfect knowledge may be better than a decision made later with perfect knowledge about all possible alternatives.

AAEA EMPLOYMENT SERVICE

Since its inception a few years ago the AAEA employment service has continued to expand and has become a major activity at annual meetings. In 1970 the president suggested that the service should not be operated when it would conflict with general sessions. For those seeking employment, strong economic interest tends to take precedence over most other affairs.

Rumors circulate at meetings and within the profession concerning applications and vacancies, the

Table 1. AAEA employment service information summary, 1970

Total applicants	256
Graduate student applicants	163
Professional applicants	93
Requests for confidential treatment	11
Bachelor's degree applicants	1
Master's degree applicants	53
Ph.D.'s or Ph.D. candidates	202

ratio of jobs to seekers, salaries, etc. This note may allay some misconceptions as well as provide information that we hope may bring improvements to our most personally important market. While the formal employment service is only the visible tip of the market for agricultural economists, it can or should be an important aspect for "freeing" a market that operates imperfectly. Making data on the employment service available should improve knowledge of the market and thereby improve its operation.

1970 Applicant Data

A total of 256 individuals seeking jobs registered with the employment service in 1970, an increase of 45 from 1969 (Table 1). Of these, 163 were graduate students while 93 were in the professional category, i.e., basically those already holding jobs but seeking a change in employment. The latter service was started in 1969 at Kentucky and can be confidential. However, only 11, about one-fourth as many as in 1969, elected to remain anonymous, although the number of applicants in the professional category increased from 48 to 93. Most applicants held doctorates or were doctoral candidates (202), while one had a B.S. degree and 53 held the M.S. or M.A. degree or were working toward such degrees. Of the graduate students, 138 of 163 applicants had not completed their degrees, while 9 of the 93 professional applicants also were degree candidates.

Applicants indicated their area(s) of specialization, with from one to several per candidate (76 listed only one area); however, no more than three were used to classify applicants in the directory prepared for employer use in 1970. These are summarized in Table 2. The classification used by Hitzhusen [1, p. 137] was used for the directory, except that the "food and nutrition" category was eliminated and "general economic theory" was made a catchall for "theory, general agricultural economics, and other" areas. The primary or first choice area breakdown was somewhat different from that reported by Hitzhusen but exhibited a similar general pattern and a continuation of some of the trends of recent years. The "theory and other" category was considerably larger for the applicants than in the general breakdown. In addition to several categories not included in the usual agricultural economics subareas (e.g., business analyst), many of those in the "other" category were persons desiring work in economics departments of smaller schools. Many who go into such jobs later drop their affiliation with agricultural economics.

"Marketing" and "farm management and production economics" remained large categories but were relatively smaller than in the 1966 classification. "Resource and regional economics" (Hitzhusen's "land and water economics, conservation, and development"), at almost double its 1966 employment proportion, ranked with "marketing and farm management-production economics." This appears to correspond to recent changes in societal goals, assuming that interest in resources is related to environmental problems. International area applicants were about the same percentage as employment in 1966. The proportion of applicants who gave as their main interest area one of the quantitative fields (statistics, econometrics, etc.) was considerably higher than the employment proportions for 1956, 1961, and 1966, as reported by Hitzhusen.

Proportions of graduate students and professionals listing the various areas of specialization generally followed similar patterns except for "farm management-production economics" and "theory and other." The proportion of graduate student applications in "farm management-production economics" was about double the professionals, 21 percent versus

12 percent; while professionals were more than twice as important relatively in the "theory and other" category.

Over 70 percent of graduate students reporting an occupational preference listed academic institutions as their choice.[1] About 17 percent listed business first and 8 percent preferred governmental employment.[2] Along this same line, 53 percent of the graduate students indicated that teaching was the most preferred type of work while 24 percent favored research. Over 70 percent of both groups listed both teaching and research within their top three preferences. Only 10 persons in both groups said that extension was the most preferred type of work, although 35 listed it among their top three preferences.

[1] Although organization preferences were indicated on the professional form, they were not in order of greatest preferences and thus cannot be compared directly with those of the graduate students. However, about 73 percent of the professionals gave academic institutions as one of their choices.

[2] Although only a relatively small percentage gave business as first preference, it was interesting to note that one industrial employer had requests for interviews from over 100 applicants on the first day of the service.

Table 4. Job openings by area of specialization, AAEA employment service, 1970

Specialization	Number of openings	Percent
Marketing	25	21.4

Finance	8	6.8
Business management	3	2.6
Total	117	100

Job Vacancies

The 117 job vacancies listed by 69 employers with the employment service in 1970[3] represent a decrease of 32 from 1969 and reflect the generally slower employment market that characterized other disciplines and the economy as a whole. Of the total, 57 percent were vacancies at universities or colleges and 26 percent were in governmental agencies. These two employer categories were over four-fifths of all vacancies listed. The balance of the vacancies were rather evenly distributed among international agencies, cooperative organizations, private industry, banks, and consulting firms, as shown in Table 3. The majority of job openings required Ph.D.-level training, although a significant number of banks and businesses indicated that an M.S. degree would suffice.

Position openings in universities and colleges were divided about equally between teaching-research

[3] Several employers registered with the employment service without listing any job vacancies and were later seen interviewing. We recommend termination of the practice of issuing courtesy passes and refusal of access to the applicant binders to anyone who had not filed at least one vacancy with the service.

and positions with at least one-half time extension. As shown in Table 4, marketing outranked other areas of specialization in the job descriptions that accompanied vacancies but was closely followed by farm management, quantitative methods, and public policy.

In general the employment market for agricultural economists was off in 1970 but nevertheless showed some firmness in comparison with other academic disciplines.

Concluding Comment

The primary market for agricultural economists, as for most of academia, operates on an interpersonal basis and is very imperfect. There is no open market, and little price information is available except on an oral basis. With the heterogeneous product and without standard grades, price information becomes difficult to interpret. The main function of the AAEA employment service is to provide the opportunity for a freer and broader exchange of information between the direct parties. This makes possible initial contacts beyond the scope of advisers, acquaintances, friends, and colleagues. To the extent that the service is utilized some of the knowledge imperfections are lessened and a freer flow of talents is enhanced. Actual use of the service for 1961–1970 is reported in Table 5.

ESTIMATES OF INCOME EFFECTS FROM WATER TRANSFERS: A CRITICAL EVALUATION OF THE HARTMAN-SEASTONE ESTIMATES FOR IMPERIAL COUNTY, CALIFORNIA

The recent book by Hartman and Seastone [1] provides a useful theoretical framework for evaluating the economic efficiency of water transfers between alternative uses in the arid West.[1] However, we take issue with the authors' empirical estimate of the value of an acre-foot of water, transferred out of Imperial County, California, presented as an illustration of empirical implementation of their theoretical model [1, ch. 8].

The authors say in the first sentence of the chapter that the estimates to be presented will give "some" empirical content to the theoretical model developed in chapter 7. At two subsequent places in the chapter (pp. 105 and 106) they caution almost parenthetically that because the empirical implementation presented is meant to be illustrative only, quantifications of some of the elements in their model are "chosen somewhat arbitrarily and without justification." Thus, by implication, they argue that the particular value of the estimate they derive is not important. We disagree. Our experience in publishing the results of water resources research has taught us that this is one area of research that is read avidly by the public (or, more accurately perhaps, by its elected and appointed water policy leaders). Because of the popularity of water resource development among both state and federal agencies and local water users, particularly irrigators, estimates of the value of an acre-foot of water, *especially if these estimates are of a large magnitude*, are quoted and requoted for consumption by the voting public.

Their use of "capitalized value" to portray the value of diverted water is an unfortunate choice. It is customary in the West to refer to the value (cost or price) of water in terms of its value (or cost) per acre-foot per unit of time (usually per year). The careless, biased, or unsophisticated reader will interpret the value of transferred water at $295 per acre-foot, as derived in this chapter, as a very "high" value, in spite of the fact that it is always referred to as the "capitalized" value of water. In fact, $295 per acre-foot is not a very "high" *capitalized* value of water as such water costs go in the Southwest for newly developed supplies of water for water-short areas. Inasmuch as transfer of an Imperial Valley water *right* is a transfer in perpetuity of a right to receive a perpetual *flow* of water and inasmuch as the discount rate used in the analysis to derive the capitalized value is 5 percent, the equivalent *annual* value per acre-foot of flow is ($295 $\times$ .05), or $14.75 per acre-foot per year. A figure of the latter magnitude of the "value of out-transferred water" would produce much less mischief than would the former in interpretation by the lay public or a biased edite.

Unfortunately, the authors themselves abet just such mischievous interpretation, falling into their own trap by explicitly drawing a policy conclusion from their value estimate (p. 108): "The order of magnitude of the above estimates [$295 per acre-

[1] A general review by Kelso of this book appears in this issue of the Journal.

foot] calls into question the desirability of large block withdrawals of water from developed agricultural areas, as some have proposed."[2]

Quite apart from the possible mischief stemming from the *form* (capitalized value) of the estimate chosen by the authors, the empirical estimates of their chapter warrant no such statement as to the desirability of the water transfer.

The analysis focuses narrowly and only on economic interdependency within California resulting from the disappearance of food and feed grains and forages from within the Imperial Valley. In terms of their own theoretical model of chapter 7, this constitutes only area A (the water-exporting area) and part of the area C ("rest of the world") effects. Similar analyses covering at least area B (the water-receiving area) and, to be complete, the rest of the area C effects as well are not included, nor even alluded to. Regardless of the magnitude of any derived value of out-transferred water in the area of its origin, no policy implications of any sort can be drawn from it (except maybe how much the selling area should be "paid" for it to cover its "losses"); policy conclusions concerning a transfer are possible *only* if area B and C effects are also evaluated. Not only was no such analysis made of these area effects, what is more critical, the authors did not even mention in chapter 8 that such empirical analyses would be necessary before policy implications concerning water transfer out of the Valley could be drawn.

Immediately following the above quote relating to policy implications, the authors added [1, p. 108], "It seems doubtful that any manipulation of data or assumptions would radically alter the order of magnitude of the above estimates."

We turn now to those questionable assumptions and to those omissions from their analysis that call into question the validity of this second statement. We begin by recalculating the authors' own estimates, retaining their key assumptions but modifying several points in their data interpretations: (1) their unexplained exclusion of all taxes from household income which, following their explanation of coefficient derivation [p. 97], we restore to the profit coefficients and thus raise their estimate of water value; (2) their use of water coefficients pertaining to California as a whole (obtained from [5]), for which we substitute those derived by us for Arizona [4] (which more nearly reflect the arid but irrigated conditions of the Imperial Valley) and thus lower their estimated water value; (3) their unexplained elimination [1, p. 105, Table 10] of all indirect profits in the feed and forage sector (which implies they are 100 percent recoverable), for which we substitute their estimate [1, p. 106] of 48 percent nonrecoverability and thus raise their value estimate; and (4) their unexplained implied assumption that 48 percent of indirect profits in the "other" sectors [1, p. 105, Table 19] is unrecoverable which is their estimate of unrecoverability in the feed-forage and livestock feeding sectors, for which we substitute 25 percent—their estimate for unrecoverability in the processing sector—which we argue more nearly reflects conditions in the other mostly nonagricultural sectors. This adjustment lowers their estimate of water values. Without presenting all the calculations and changes, these modifications of their data interpretations result in a revised estimate of the capitalized value of out-transferred water of $296.27 per acre-foot in place of their of $295.36, a change of inconsequential magnitude. Thus we confirm part of the authors' contention, viz., that alterations in the manipulations of the *data* do not radically alter the order of magnitude of the value estimate. This net result is merely fortuitous; for example, if one adjusts only the water coefficients, the Hartman-Seastone estimate is reduced by about 9 percent. Changing the assumption on percentage recoverability of other profits lowers their estimate by about 7 percent. Adding grain and forage profits has a 3 percent positive effect. The tax assumption has an upward effect of 13 percent.

However, manipulation of some of their key assumptions and inclusion in the analysis of some elements that they ignore *do* materially affect the order of magnitude of their estimated value of water. To these we now turn.

A crucial assumption of the Hartman-Seastone argument is that if water were transferred from use in the Imperial Valley to use in Los Angeles County by amounts that increase at the rate of 32,900 acre-feet per year as required by the Los Angeles area, all grain and forage crops would disappear in Imperial County in some 30-plus years. At the same time, because the livestock feeding, dairy, poultry, meat and poultry processing, and grain mill products industries are based on the local production of grains and forages, these industries would also completely disappear. Estimates of the direct and indirect effects of these disappearances were made with the aid of the input-output model of the 1954 California economy [3].

Our major disagreement with their analysis is on the basic assumption that all of the livestock and livestock processing industries would disappear as local grain and forage crops are phased out. If these industries were to remain, as we believe they would, the value of an acre-foot of out-transferred water would be materially reduced.

The only evidence given for this all-important assumption is a statement in a previous theoretical chapter [1, ch. 7, p. 82]: "It is generally recognized that locational advantages are gained by locating the feed yards and packing plants near the feed-forage supply, *other things equal*."[3] This statement was supported by a footnote as follows:

[2] At this point, the authors reference Hirschleifer et al. [2].

[3] Emphasis added.

This conclusion was affirmed by Professor David Seckler at Colorado State University who is part owner of a vertically integrated irrigated cropland-feed-yard-packing plant operation located at Sterling and Wray, Colorado. Hugh Winn, livestock marketing specialist at Colorado State University, also affirmed this conclusion and provided additional information on the competitiveness of this industry.

We do not disagree with the quoted authorities. We only argue that in the arid Southwest, *other things are not equal.* In the Imperial Valley, as in Arizona, cattle feeding has a comparative advantage in livestock feeding which is independent of local feed production. Both areas have high efficiency of feed conversion due to the hot, dry climate. Both are near large centers of population in which to market their product. Both already import large quantities of feed grains from the Southern Great Plains. (Arizona, while a net grain exporter, has traditionally exported most of its local supply and imported the grain it actually feeds.) Feed grain and forage prices in the Imperial Valley and in Arizona are now dominated by their price in the deficit areas of California less cost of transportation. Forage is becoming a less important input into the feeding industry at the same time that pelleting technology is reducing its transportation and handling costs. Hence, it may be plausibly deduced that the livestock feeding and processing industry in the Imperial Valley is not dependent on locally grown feed grain and forage supplies but upon the comparative advantage of its feed conversion ratios and the existence of a deficit feed grain and forage demand in the Los Angeles basin and central Californa.[4]

Therefore, we have made alternative estimates of the value of an acre-foot of out-transferred water under our alternative assumption—that the indirect effects on the Imperial Valley economy would include only the backward linkages from the disappearance of forage and feed grains and not the forward linkages assumed in the Hartman-Seastone analysis.

Once the assumption of only backward linkages is recognized, Table 18 and Figure 11 of Hartman and Seastone become almost irrelevant. They lead to some confusion [1, pp. 103–104] even for the purpose of their own analysis. Their Table 18 lists the direct and indirect total water use per year resulting from deliveries to *final demand* of all the agricultural sectors in the area. Attached to these estimates are rent, profits, and wage estimates in dollars per acre-foot per year, the sum of the products of which lead to an estimate of total "value added" generated annually by total water use in the area. Figure 11 graphs the results of Table 18.

The confusion can be generated if the lay public compares water totals to value totals to obtain an *average* value per acre-foot per year. This would be approximately $154 per acre-foot per year for all agricultural industries in the region. Even under the forward linkage assumptions, only food and feed grains, livestock group, and grain mill products sectors are at the margin where, if they were all totally eliminated, an average annual value would be relevant. This value would come to about $89 per acre-foot per year (using Hartman and Seastone original estimates). Much of this value is recoverable, and so the final unrecoverable value per acre-foot per year (including unrecoverable wages lost) if total disappearance occurred would be about $14.75 ($295.36×.05) [1, Table 19 and p. 107].

If, as we assume, only backward linkages occur, our Tables 1, 2, and 3 present the relevant information. Table 1 shows that $29,453,000 of gross output per year are generated by the two marginal sectors using 1,332,201 (our estimate) acre-feet of water per year. Average *direct total value* (not value added) is only $22.11 per acre-foot per year. The data in Tables 2 and 3 (col. 2) show that direct value added per year is $14.12 for food and feed grains and $14.70 for forage. Indirect value added generated annually from backward linkages is $4.97 for grains and $4.70 for forage. Thus total direct and indirect value added per acre-foot per annum is $19.09 for grains and $19.40 for forage.[5]

Table 1. Total output and water use for the affected sectors

Sector	Gross domestic output	Total direct water use: Hartman-Seastone estimate	Total direct water use: Our estimate
	thousand dollars	*acre-feet*	
1. Food and feed grains	10,375.9	241,862	436,722
4. Forage	19 077.1	890,519	895,479
Total	29 453.0	1,132,381	1,332,201

[4] Research is under way at Arizona to empirically test this hypothesis.

[5] The income multipliers on which Tables 2 and 3 are based are "adjusted" income multipliers since they are related to per dollar changes in output rather than per dollar changes in final demand. The difference is explained in [3, p. 14] as follows: ". . . interdependence coefficients (A_{ij}) may be 'scaled down' to reflect only the direct and indirect effects of *output changes* by dividing each column entry . . . by that column's diagonal element. That is, each A_{ij} is divided by its corresponding A_{ij} for $i=j$. The result is to net out internal flows (requirements from industry i by industry i) generated by final demand for industry i as well as further flows from other sectors induced by these internal flows. Output requirements from industry i per dollar of final demand for industry i are now exactly one dollar. Output requirements from other sectors per dollar of final demand for industry i are thus, in effect, per dollar of output of industry i." Adjusted multipliers were used since it is the decrease in output rather than the decrease in final demand that is being measured under our backward-linkage-only assumption. The result was to scale

Table 2. Food and feed grain income multipliers and estimates of capitalized income losses, assuming backward linkages only

Income component	Income multiplier[a]	Income per acre-foot[b] per year	Unrecoverable income per acre-foot per year	Capitalized income flow[c]	Capitalized income flow[d]
			dollars

Profits					
Direct	.136	2.89	1.39[f]	17.32	13.65
Indirect	.077	1.64	.41[g]	5.11	4.03
Total				128.63[h]	84.06[i]

[a] Value added, by component of value added, per dollar of change in *output* of the food and feed grain sector.
[b] Income multiplier divided by revised water coefficient of .0471.
[c] Assuming planning horizons of infinity and 20 years of land rent and profits, respectively, capitalized at 5 percent.
[d] Assuming planning horizons of 20 years and 14 years for land rent and profits, respectively, capitalized at 5 percent. This assumption is equivalent to the same planning horizons as under (c) above, but using a capitalization rate of 8 percent.
[e] A total one-shot wage loss of $4.78 (one-half year's wages).
[f] Forty-eight percent of col. 2 entry.
[g] Twenty-five percent of col. 2 entry.
[h] $128.63 of capitalized income flow plus $4.78 for six months of wages lost gives a total value of $133.41 per acre-foot of perpetual right to one acre-foot of water per year.
[i] $84.06 of capitalized income flow plus $4.78 for six months of wages lost gives a total value of $88.84 per acre-foot of perpetual right to one acre-foot of water per year.

As Hartman and Seastone point out, much of this foregone income would be recoverable as water is transferred from these uses to others. Using their procedure, we estimate nonrecoverable income to be $7.41 per acre-foot per year plus a one-shot wage payment of $3.48 for grains and $6.43 per acre-foot per year plus a one-shot wage payment of $4.78 for forages.

When these annual values are capitalized at 5 percent (to infinity for land and over 20 years for capital facilities), these values plus the one-half year loss of wages income become total values of $151.75 (footnote h, Table 2) for grains and $133.41 (footnote h, Table 3) for forages per acre-foot of perpetual right to one acre-foot of water per year. Because these are capital values of the right to receive an acre-foot of water per year in perpetuity and the discount rate used in their derivation is 5 percent, the value of an acre-foot of flow per year used for these purposes is ($151.75×.05) or $.7.59 for grains and ($133.41×.05) or $6.67 for forages, values materially lower (half or more) than those estimated by Hartman and Seastone.

In the concluding paragraphs of their chapter 8 they say, "It is quite obvious that the critical *assumptions concern the amount of immobility in capital, land, and labor resources*."[6] They are correct, of course, but, as indicated above, they should have added "and the substitutability of other inputs to the processing sectors for those that will disappear from local production." They do mention the importance of input substitutability in such analyses in their theoretical chapter 7 [1, p. 83] and again in their final conclusions [1, ch. 9, pp. 123 and 124], but they choose to ignore it, by assumption, in their empirical chapter 8

Another of the key assumptions in the Hartman-Seastone analysis is a discount rate of 5 percent applied to land rent to an infinite horizon and to depreciable and unrecoverable capital facilities to a 20-year horizon. We consider their assumption of 5 percent to be acceptable as an opportunity interest rate as a current earning demand on investments in unrecoverable land and capital facilities. We consider it highly dubious, however, that the expected earning capacity of these assets should be capitalized at this rate to planning horizons as distant as infinity and 20 years respectively, due to risks and uncertainties, even by the public sector. Let us alter their assumption by the plausible presumption that land rent would be capitalized to a 20-year horizon at 5 percent (equivalent to an 8 percent discount rate in perpetuity). In like manner, let us assume the same implied 3 percent "risk and uncertainty" discount rate on depreciable unrecoverable capital facilities and thus use 8 percent for 20 years to capitalize the income flowing from these assets. (This is equivalent to current earnings of 5 percent for a shorter period of approximately 14 years.)

Substituting these capitalization factors into the calculations in Tables 2 and 3, we derive capitalized water values (including wage losses) of $101.58 per acre-foot for grains and $88.84 for forage, as shown in footnote i of Tables 2 and 3, respectively. Because these are present values for a perpetual right to receive one acre-foot of water per year and because the opportunity cost interest rate for current earning from this investment is taken to be 5 percent, the average annual equivalent value of this water flow to an infinite horizon is ($101.58×.05) or $5.08 per acre-foot for grains and ($88.84×.05) or $4.44 for forages.

Again the significance of altering a key assumption in the estimates is revealed. The estimated value of an out-transferred acre-foot of water has been reduced by a third merely by altering the assumed capitalization horizon.

But there is another side to the argument. There are elements in the value of an acre-foot of out-transferred water that Hartman-Seastone did not include in their estimate. Including them will alter estimates upward. They mentioned two such omissions—the effect of the houshold consumption multiplier and the accumulative effect on the public sector through loss of tax revenues and reduction in use of public facilities. In our above revisions of their estimates, we have partly corrected for one of these omissions by adding taxes paid back into the estimates of incomes lost. Thus the loss of tax revenues is allowed for in our revised estimates although the effects of the balance of these omissions are not.

But of much greater importance among omissions from their estimates is one not even mentioned by them, although the basis for its inclusion was explicitly laid down by them in their theoretical model in chapter 2. That omission is the impact on the Salton Sea following upon transfer of irrigation water out of the Imperial Valley. The sea is a recreational resource experiencing rapidly growing demand largely from southern California coastal residents. It is fed largely by return flow from irrigation in the Valley. As conceptualized by the authors in their chapter 2, the recreational industry on the Salton Sea may experience a "technological external diseconomy" which must be included in any measure of the cost of transfer. Doing so could be expected to increase the derived value of out-transferred water.

Where does all this leave us? With a mixture of paradox and incompleteness that may lead to much mischief in the hands of the unwary, the unsophisticated, and the unethical. The incompleteness arises from the numerous omissions from their analysis (most important from the standpoint of policy implications being the total omission of any reference

---

down the output multipliers to 95.7 percent and 99.8 percent of their original values for grains and forage, respectively.

[6] Italics in the original.

to, let alone estimate of, the value of transferred water to the receiving area and to the "rest of the world") and from the debatable character of some of their key assumptions. The paradox arises from the apparent circumstance that were we to go to all the trouble to alter data interpretations and key assumptions and to include omitted elements in the estimates of water transfer values to the Imperial Valley, we might come out with an estimated value not far from the Hartman-Seastone estimate. But, of course, this really is no paradox; it is but a circumstance coincident to the empirical conditions of the Imperial Valley.

What we really are left with is total ignorance of the economic efficiency of a transfer of water out of the Imperial Valley to the California coast and a wholly inadequate estimate of the value of out-transferred water even to the Imperial Valley economy itself.

Thus may mischief arise due to the sanctity with which such estimates are clothed by virtue of their formalization in print under the professional aegis of two capable and reputable economic analysts and the highly respected imprimatur of RFF. From these considerations arose Kelso's concluding sentence of his review of the Hartman-Seastone book, "This reviewer wishes the authors had left it [chapter 8] out entirely or had developed it more cogently and completely," a wish we reiterate here.

ECONOMETRIC STUDIES OF MILK MARKETING: COMMENT

This communication reviews two recent *AJAE* articles presenting econometric analyses of portions of the dairy industry. One is Marvin Kottke's model of the New England dairy industry [4]; the other is George Ladd's analysis of federal order blend prices [5].

Both of these involve broader coverage than my own model [2], one confined to the geographic alignment of Class I prices in Federal order markets. Kottke's model uses demand functions for fluid and manufacturing milk and short-term supply response functions to predict the production and disposition of milk in four New England subregions, with upstate New York and Chicago as additional supply areas. An intriguing feature of his model is that it was started at 1965 and predictively extended through 1970, with actual data through 1967 providing a comparison of the predicted and actual outcomes.

An inherent limitation of any such analysis is the construction of demand and supply functions for the submarkets and production areas. Supply response is particularly subject to variations that depend heavily on the time period allowed and to the influences of technological changes and interregional shifts. These basic limitations are illustrated by the fact that milk production in New England declined in 1965 (and since), rather than rising as predicted by the model. Correspondingly, actual blend prices rose to a substantially greater degree than predicted.

In addition, however, Kottke appears to have made a serious conceptual error by devising demand functions for milk for manufacturing purposes in each of his four marketing areas. In practice, fluid markets try to maximize Class I uses and deal with the daily, seasonal, and annual surpluses by converting them to manufactured products as efficiently as possible and selling the products on the national market. Thus, the demand for milk for manufacturing in any given region or subregion is not a linear, down-sloping function. Rather, it is an essentially horizontal function, at about the national support price level.

There are two unrealistic effects of the assumed down-sloping demand curve for manufacturing milk and the inclusion of transportation charges on such milk. One is the unduly low price at the Chicago source. The second is that the bulk of the Vermont milk is assigned to be manufactured rather than shipped for fluid uses, with abnormally low blend prices as a result.

Ladd used historical data to analyze the effect on intermarket differences in blend prices of such fac-

tors as distance from Eau Claire, Wisconsin, percentage of producer milk used in Class I, changes in dairy support levels, supply-demand adjusters, individual handler pooling, and economic index formulas for determining Class I prices.

Ladd and I concur with a 1962 conclusion of the Federal Order Study Committee: "The practice of varying the terms of the orders from market to market tends to magnify these problems of intermarket relationships." I have emphasized Class I price alignment, since these prices are specifically determined by order provisions. By contrast, blend prices on which Ladd centers his attention depend also on the percentage of producer milk used in Class I and are subject to influences outside the scope of regulation.

Ladd's use of 1959–1962 data is a serious shortcoming for an industry and a regulatory program that are changing so rapidly. Moreover, it was not necessary to use such ancient data; the information on price support removals published in his Table 2 has regularly been published by USDA. For example, the *Dairy Situation* for May 1969 carries this series of annual data for the period 1949 through the 1968–69 season. Moreover, this is only one of his minor inputs, so should not have been allowed to so severely outdate the entire analysis.

The reliance on a model using Eau Claire-plus-transportation cost is equally archaic. This is not to detract from Louis Herrmann's pioneer effort [3] which preceded the ready availability of more sophisticated computer models. West and Brandow's spatial equilibrium model published in this Journal in November 1964 [6], Carley and Purcell's reactive programming model of 1965 [1], and mine of April 1968 take into account multiple sources of supply and demand, thus yielding more realistic measures of intermarket price alignments than the Eau Claire model. Eau Claire-plus-freight provides only an upper limit influence on prices in other markets.

There are other defects in the analysis that are only moderately less serious than the age of the data or the reliance on Eau Claire as a base. In equation (1), attributed to Babb, there is no term X_{i2}, but a definition is given for this nonexistent term. A serious conceptual error is contained in the equation on page 628, relative to Class II price. His equation reflects distance from Eau Claire, seasonal factors in the Class I price, and various other Class I price components. Actually, Class II prices have always been set as closely as possible to national manufacturing values, with a minimum of local differences. Such differences as have been allowed reflect efficiencies in manufacturing operations rather than the types of differential that have applied to Class I prices. This misconception of the nature of the Class II price is built into formula (2) and affects the entire subsequent analysis.

Finally, it is a conceptual error that in any given order or group of orders, supply-demand adjusters could "have cushioned the price-depressing effects of decreases in X_4," X_4 being the Class I utilization percentage. It could conceivably be true that a group of orders without supply-demand adjusters may have shown more variation in blend prices than a group having such adjusters. This could occur as a result of such other factors as the presence or absence of economic formulas. However, a supply-demand adjuster geared to the percentage of the supply used in Class I would, by virtue of the arithmetic involved, raise blend prices more rapidly when a shortage develops than if there were no supply-demand adjuster.

These two cases illustrate the fact that econometric studies place heavy demands on reviewers and readers in identifying the symbols, checking the mathematical manipulations, and evaluating the assumptions involved at each step of the process. Kottke's model was exceptionally well presented; it was easy to obtain a visual representation by graphing the supply and demand functions. Ladd's article, on the other hand, shows little evidence of careful review by anyone with a working knowledge of federal orders or of the price support programs.

ECONOMETRIC STUDIES OF MILK MARKETING: REPLY

Robert Freeman has raised an interesting issue regarding the conceptualization of pricing behavior in the manufacturing milk market. The issue is whether or not to allow for a regional demand influence on price in a spatial allocation model. Freeman argues that he would not make such an allowance. He suggests that demand in any given region is "an essentially horizontal function," i.e., price is taken as given and any quantity offered can be sold in the market at that price. I contend that all regions face a potential limit in the form of price response and, characteristically, such a limitation is conceptualized as a "down-sloping" demand function.

Freeman's suggestion seems to be based largely on the mechanics of pricing. It is true that, in reality, Class II milk prices are computed in each federal order market by using a national basepoint price such as the Minnesota-Wisconsin "milk price paid to farmers." However, it does not follow that the price-making forces that determine the Minnesota-Wisconsin prices reside exclusively in the Minnesota-Wisconsin area. Moreover, milk processors and distributors can hardly ignore consumer price responsiveness in their own markets even though a national market prevails.

Apparently, Freeman's concentration on "slopeless" regional demand functions caused him to overlook the possibility that the two alleged "unrealistic effects" were caused by errors on the supply side, rather than by an assumption of "down-sloping" demand functions. The low milk price for the outside region is, admittedly, unrealistic. However, it resulted from an overestimation of the outside region's milk supply—not from the form of the demand functions. The second effect, that the bulk of Vermont's milk was allocated to manufacturing uses, is not unrealistic. Vermont's milk supply chronically exceeds demand from neighboring fluid markets, and consequently over half of its supply is utilized as manufacturing milk. The reason for Vermont's "abnormally low" solution blend price existed elsewhere in the model. I discovered that the cause was an underestimation of Vermont's Class I price, and this error has been corrected in subsequent applications of the model.

Although I do not subscribe to Freeman's view of a milk market calling for slopeless regional demand functions, I do share his concern that regional manufacturing milk prices should reflect the price support level. Conceptually, this can be done by including a governmental purchasing activity and, since the multistage model incorporates a time dimension, the storage function associated with a price support program can be included.

MARVIN KOTTKE

ECONOMETRIC STUDIES OF MILK MARKETING: REPLY

Freeman's first criticism of my paper [1] concerns the age of my data. I wanted data for a four-year period in which support price levels and removals (as percentages of marketing) changed substantially between the second and third years and changed little between the first and second and between the third and fourth years. Four years were desired rather than two to obtain greater statistical reliability. Years more recent than 1959–1962 that satisfy these criteria are so recent that necessary data for these years were not available when the study was started. I explained this in my paper. The second sentence in the first paragraph on page 631 probably should have read: "U. S. Department of Agriculture purchases of milk solids and support price levels rose substantially between 1959–60 and 1961–62."

Freeman next complains that the model I used is archaic. Archaic though the model may be, it was not inappropriate for my purposes. The objectives of Freeman, of West and Brandow, and of Carley and Purcell were to find *equilibrium* levels of prices, or of consumption, or of production, or of all three. As I stated on page 625, my objective was to measure *existing* relationships and to test hypotheses concerning these relationships. For their objectives, my procedure would have been inappropriate; for my objectives, their procedure would have been inappropriate. One of the very features that made their procedures appropriate for their objectives renders their procedures inappropriate for my objectives, namely, abstracting of institutional relations from programming models.

We need to remember that all models are inappropriate; different models are simply inappropriate for different things.

As to the complaint that X_{i2} does not appear in equation (1), perhaps my exposition would have been clearer if I had multiplied β_2 by X_{i2} in my equations so that (1), for example, would have read

$$Y_i = \beta_2 X_{i2} + \beta_3 X_{i3} + \beta_4 X_{i4} + \epsilon_i$$

This may have been a presentational defect, but it was not an analytical defect.

Freeman objects to my relation (appearing on page 628):

$$P_{i2} = f_2(X_{i3}, X_{i4}, \cdots, X_{i10})$$

Apparently he would have preferred the relation

$$P_{i2} = F_2(\bar{P})$$

where $\bar{P}$ is national annual average manufacturing milk price. Since $\bar{P}$ has the same value for every market, it cannot account for intermarket differences in prices. Since my purpose was to analyze intermarket price differences, the inclusion of $\bar{P}$ in (2) would not have contributed anything to my analysis.

Neither theory nor previous empirical work tells us what form functions such as equation (2) should be. I chose to estimate (3) because (a) it allows for interaction effects and (b) it is a simple functional form. Even if my expression for P_{i2} were replaced by $P_{i2}=F_2(\bar{P})$, these two criteria would still have led me to use equation (3). This replacement would not have changed any of the hypotheses listed in Table 3 on page 632; neither would it have changed anything from page 633 to the end of the paper. This replacement would have made the βs in equation (3) functions of $\bar{P}$. Any effect of variations in $\bar{P}$ can be reflected only in analyses containing data for more than one year. During 1959–1962, annual values of $\bar{P}$ were closely related to annual price support levels and to annual price support removals from the market. I tested for effects of changes in the price support program on the βs by using F tests [1, Table 4, page 633] and by allowing intercepts to vary among years [1, Table 5, page 634].

Hence, even if I accept his proposition that formula (2) is based on a "misconception of the nature of the Class II price," I do not accept his conclusion that "this misconception . . . affects the entire subsequent analysis." And, having seen no evidence on the relation of P_{i2} to $X_{i3}, X_{i5}, \cdots, X_{i10}$, I am not convinced that (2) is based upon a misconception; I am ready to admit that it may be.

My first response to his statement concerning the "conceptual impossibility" of the effects I attribute to supply-demand adjusters on page 636 is to paraphrase Hamlet (Scene V, Act I) when he says,

> There are more things in heaven
> and earth, Horatio,
> Than are dreamt of in your
> philosophy.

My paraphrase is:

> There are more things in heaven
> and earth, Mr. Freeman,
> Than are explicable by our
> economic concepts.

Or, in less elegant language:

> What is to be will be,
> What ain't to be might happen.

The fact that something is "conceptually impossible" does not make it "factually impossible." Granted, my statistical results and my interpretation of them are not consistent with our conception of what supply-demand adjusters *ought* to accomplish. I wish that in addition to rejecting my interpretation of the relation $\Delta Y/\Delta X_4 = 0.026-0.004X_{10} + \cdots$, Mr. Freeman had presented us a conceptually correct interpretation of the inconsistency between theoretical expectations and empirical results.

I cannot agree with his contention that differences I have attributed to supply-demand adjusters are due to other differences in order provisions. My equations contained "such other factors as the presence or absence of economic formulas" and other differences in order provisions. If orders without supply-demand adjusters showed more variation in blend prices because of other factors, the coefficients of these other factors (not of supply-demand adjuster) should explain the difference.

As my acknowledgments indicated, earlier drafts of my report were read by Emerson Babb, Alden Manchester, and J. R. Strain. I certainly do not agree that these people lack a "working knowledge of federal orders or of the price support program." Whether they reviewed the manuscript carefully I cannot say, but I know that they provided some helpful criticisms. A number of the comments of the anonymous reviewers for this Journal lead me to believe they know a good deal about federal orders and that they had read the manuscript carefully.

It may be, of course, that my paper "shows little evidence of careful review" because I failed to incorporate the best suggestions of the reviewers and editors into the final draft.

POSITIVISTIC MEASURES OF AGGREGATE SUPPLY ELASTICITIES: SOME NEW APPROACHES—SOME CRITICAL NOTES

The analysis of supply made by Tweeten and Quance [1] is of special methodological interest for econometric analyses using least squares. The purpose of this note is to show that the authors' method of solution is mathematically incorrect both for (1) quantification of irreversible supply reactions to in-

creasing and decreasing prices and (2) differentiating the partial influence of an independent variable during certain periods of investigation.

The Problem of Irreversibility

The problem of irreversibility is not limited to price-supply relations but is of fundamental importance for analysis of many economic relations. However, the use of least squares or related methods of estimation which assume reversibility of relation creates especially serious problems in estimating demand and supply functions. Specifically, inclusion of one or more irreversible independent variables into a function affects the analysis in two respects:

(1) The partial influence of each independent variable cannot be determined exactly;

(2) The coefficients of all other independent variables can be distorted—even a change of signs is possible [2, p. 8].

Tweeten and Quance have treated the irreversible reaction of supply to price changes by splitting the price variable into one variable for increasing prices and another variable for decreasing prices. Their method of splitting variables is described as follows: "When $P_r/P_p{}^{t-1}$ is for a specified period or for years of declining or increasing prices, it is the actual observation for the specified years but has a zero value for other years in the period observed (1957–59 = 100)" [1, p. 343].

It can be proved, however, that the quantification of irreversible relations cannot be done by this method. Supposing that the residual variance = 0, the case of reversibility is shown in equation (1):

$$(1)\quad y_i = a_0 + a_k x_{ik} \qquad \text{for } i = 1, \cdots, n \text{ and } k = 1, \cdots, m$$

y = dependent variable

a_0 = additive constant

a_k = coefficient of regression

x_k = independent variable

Applying the splitting procedure suggested by Tweeten and Quance, equation (1) can also be written as

$$(2)\qquad y_i = a_0 + a_k x_{ik}' + a_k x_{ik}''.$$

Variables x_k' and x_k'' stand, respectively, for the increasing and decreasing phase of variable x_k, where

$$x_{ik}' = 0, \text{ if } x_{ik}'' > 0 \quad \text{and} \quad x_{ik}'' = 0, \text{ if } x_{ik}' > 0.$$

Because of the assumed reversible relation between y and x_k the coefficients of regression a_k of variables x_k' and x_k'' are equal; hence it also follows that a_0 as defined within the system comprising n equations is constant.

In the case of reversibility this method of variable splitting is absolutely correct. Its application, however, is unnecessary since it gives no additional information.

Given an irreversible relation between y and x_k, equation (2) becomes (3):

$$(3)\qquad y_i = a_{i0} + a_k' x_{ik}' + a_k'' x_{ik}'',$$

where

$$a_k' \neq a_k''.$$

Depending on whether in the particular equations $x_i'{}_k > 0$ or $x_i''{}_k > 0$ (the corresponding value of the other variable being equal to zero), the n equations may give rise to a maximum of n varying a_0 values. In constrast, a_0 represents a constant in the solution, obtained on the basis of the method of least squares. This deviation of the estimated a_0 value from the real a_{i0} values of the particular equations causes an incorrect estimation of parameters a_k' and a_k''. An exception is given in the case of irreversibility between the dependent and independent variable but where the independent variable shows fluctuations in only one direction.

The following describes briefly a method of solution for the mathematical treatment of irreversible reactions, applying the method of least squares [2, p. 14], which also splits the respective independent variable into an increasing and a decreasing phase, thus complying with the following requirement: The variance of the dependent variable explained by the two newly formed variables has to correspond to the actual variance which has been caused by the particular independent variable.

The splitting procedure is based on the calculation of first differences (Δx_{jk}) of observation values of the independent variable:

$$(4)\quad \Delta x_{jk} = x_{ik} - x_{i-1,k} \qquad \text{for } i = 2, 3, \cdots, n \text{ and } j = 1, 2, \cdots, n-1$$

The $n-1$ first differences which occur (n = number of observation values) are used for the formation of a x_k' variable for the increasing and a x_k'' variable for the decreasing phase.

Considering the above condition, the following should be demanded of variables x_k' and x_k'':

(1) In each case the opposite effect must be completely eliminated. This is done by

(a) separation of Δx_{jk} into $\Delta x_{lk} \geq 0$ and $\Delta x_{rk} \leq 0$;

(b) the use of $x_{ik}' = x_i'{}_{-1,k}$, if $\Delta x_{jk} \leq 0$ and of $x_{ik}'' = x_i''{}_{-1,k}$, if $\Delta x_{jk} \geq 0$.

(2) The number of observation values must remain constant; by realizing (1), this condition is fulfilled.

(3) The sequence of rates of change and thus the position of the respective positive or negative changes within the sequence may not be altered.

Starting from these requirements the formation of the two variables is effected in the following manner:

The x_k' variable is formed by adding the first differences $\Delta x_{lk} \geq 0$ to an initial value which can be any value ≥ 0. It is advisable, however, to start from the first observed datum of the initial variable that enables the identification of the initial variable.

Table 1. The data of the model

Original variables		Splitting of x-variables according to:			
		Tweeten and Quance		Wolffram	
y	x	x'	x''	x'	x''
20	10	10	0	10	10
35	13	13	0	13	10
29	11	0	11	13	12
44	14	14	0	16	12
59	17	17	0	19	12
44	12	0	12	19	17
35	9	0	9	19	20
70	16	16	0	26	20
90	20	20	0	30	20
84	18	0	18	30	22

The mathematical procedure is summarized in the following system of equations:

$$\begin{aligned} x'_{1k} &= x_{1k} \\ x'_{2k} &= x'_{1k} + \phi\,(x_{2k} - x_{1k}) \\ x'_{3k} &= x'_{2k} + \phi\,(x_{3k} - x_{2k}) \\ &\vdots \\ x'_{ik} &= x'_{i-1,k} + \phi\,(x_{ik} - x_{i-1,k}) \\ &\vdots \\ x'_{nk} &= x'_{n-1,k} + \phi\,(x_{nk} - x_{n-1,k}) \end{aligned}$$

x_{1k} = first data of initial variable x_k

$$\phi = 1 \quad \text{if } (x_{ik} - x_{i-1,k}) > 0$$
$$\phi = 0 \quad \text{if } (x_{ik} - x_{i-1,k}) < 0$$

Starting from $\Delta\ x_{rk} \leq 0$, the x_k'' variable is prepared in an analogous way. Thereby the addition of the first differences $\Delta\ x_{rk} \leq 0$ to an initial value can be effected, considering the sign or absolute value.

$$\begin{aligned} x_{1k}'' &= x_{1k} \\ x_{2k}'' &= x_{1k}'' + (1 - \phi)(x_{2k} - x_{1k}) \\ x_{3k}'' &= x_{2k}'' + (1 - \phi)(x_{3k} - x_{2k}) \\ &\vdots \\ x_{ik}'' &= x_{i-1,k}'' + (1 - \phi)(x_{ik} - x_{i-1,k}) \\ &\vdots \\ x_{nk}'' &= x_{n-1,k}'' + (1 - \phi)(x_{nk} - x_{n-1,k}) \end{aligned}$$

The computed coefficients differ only with respect to the sign. The transformation of data into logarithms should be done before the variables are split.

With the model of an assumed irreversible relation between the dependent and independent variables, where the residual variance $=0$, it can be demonstrated that the estimation equation cannot be determined exactly with the procedure suggested by Tweeten and Quance [1, p. 343].

The general function of this model

$$y = f(x) \tag{5}$$

is based on the following equation:

$$y_i = a_0 + 5x_i' + 3x_i'' \quad (R^2 = 1) \tag{6}$$

In equation (6) the independent variable x has been split into the increasing phase x' and decreasing phase x''. The initial data of the model, as well as the variables resulting from the corresponding splitting procedure, are shown in Table 1.

Applying the procedure of Tweeten and Quance for the splitting of variables, the following estimation equation (7) results:

$$y_i = -43{,}16 + 6{,}25x_i' + 6{,}99x_i'' + u_i \quad (R^2 = 0{,}912) \tag{7}$$

u_i = residual variance

Both regression coefficients differ greatly from the assumed coefficients of the model; thus, $R^2 < 1$. On the other hand, the coefficients can be determined by the proposed method of forming the variables x' and x'' of the first differences of the original variables, as shown by equation (8):

$$y_i = 0 + 5x_i' - 3x_i'' \quad (R^2 = 1) \quad (u_i = 0) \tag{8}$$

The Splitting of Variables into Partial Time Periods

Attempts to quantify the differing influence of an independent variable in various periods under investigation by "segmentation" of the variable has also been done by other authors. The number of the newly formed variables corresponds in this case to the number of periods, where the particular variables are so constructed that the respective period of analysis contains the actual values observed, whereas all other serial values are set equal to zero [1, p. 345].

The application of this splitting procedure is mathematically correct only if the coefficients of regression in the individual periods are equal, that is, if the influence of the independent variable over the total period of investigation is constant. Segmentation of this kind—according to the method of solution suggested by Tweeten and Quance regarding irreversibility—is proved useless, as it does not furnish any additional information. Where the effect of a variable is not constant over time, coefficients for all individual periods cannot be determined exactly, as the constancy of the additive constant is not given in such a system of equations. This problem is comparable to the one of irreversibility.

This procedure becomes practical with the following alteration: Instead of zeros, the lacking serial values at the end and beginning of the newly formed

variable are replaced by the last observation value of each preceding period. The alteration of influence can be regarded also in calculating with moving periods over a shorter period of time.

Summary

This note proves that Tweeten and Quance [1] applied a mathematically inexact procedure of quantifying irreversible relations between the dependent and independent variables on the one hand and the varying influence of an independent variable during a time of investigation on the other hand. The author [2] offers two methods of solving the two problems.

RUDOLF WOLFFRAM
Universität Kiel, West Germany

References

[1] TWEETEN, LUTHER G., AND C. LEROY QUANCE, "Positivistic Measures of Aggregate Supply Elasticities: Some New Approaches," *Am. J. Agr. Econ.* 51:342–352, May 1969.

TECHNIQUES FOR SEGMENTING INDEPENDENT VARIABLES IN REGRESSION ANALYSIS: REPLY*

Wolffram's technique for handling segmented variables is clearly superior to the approach we used in equation 7 of our supply response study [1, p. 344]. We had not found his approach presented in the literature and it is a significant methodological contribution, one which econometricians should consider in future efforts to segment variables.

Our reply deals with two issues. One is the recommendation that a dummy 0–1 variable be added to allow for different intercepts as well as slopes of supply curves with increasing and decreasing prices. The second is to apply Wolffram's technique to our supply data in an attempt to improve on our previous estimate of equation 7.

Allowing Different Intercepts

A variation of the Wolffram example is presented in Table 1. His example contained a single independent variable with a zero intercept and thus a unitary elasticity. Equations 1 and 2 apply the Tweeten-Quance (T-Q) and Wolffram (W) techniques respectively to the hypothetical data presented by Wolffram, except that a constant is added to the dependent variable. In keeping with the hypothesis of a different response to increasing and decreasing values of X, the constant was taken as 3 for increasing observations of X and 5 for decreasing observations. Adding the two constants prohibited either the T-Q or W model from predicting the true constants, and the equations also failed to exactly estimate the true coefficients of X' and X''. But the W parameter estimates were much closer than the T-Q estimates.[1] And the W model resulted in an R^2 of 1.00 compared to .95 from the T-Q model.

The different constants are accounted for in equations 4 and 5 by inserting a dummy variable D with a value of 1 for decreasing observations of X and 0 for increasing values of X. The W model predicts the true parameters in equation 4, whereas the T-Q estimates in equation 5 err about the same as in equation 1.

To add further realism to the example, a second independent variable, V, highly correlated with $X(r=.95)$, was added to equations 3 and 4. The results are not shown, but the W model again predicted the true parameters whereas the T-Q estimates erred greatly. To bring our example more into line with reality, a random element from a normal distribution with zero mean and a variance of 2 was added to the output variable Y. The results are similar to the above findings. All the resulting estimates deviated somewhat from the true parameters, but the W estimates again were more accurate than the T-Q estimates.

In the several equations estimated and described above, the coefficients of X' and X'' in the T-Q model tended to be equal, contrary to their true values. This raises doubts about the usefulness of the T-Q model in testing for differences in the coefficients.

Application of Wolffram Techniques to Actual Supply Data

The important question now is whether the promising Wolffram technique could improve our supply response estimates. To answer this question, we estimated equation 7 from our original paper [1,

* Journal Article 2127, Oklahoma Agricultural Experiment Station. Views and estimates presented are the authors' and are not necessarily those of the U. S. Department of Agriculture. We extend our appreciation to Lester V. Manderscheid for useful comments on this subject.

[1] The Wolffram model results in the "wrong" sign on the estimated parameter for the decreasing value of X because of the way the variable is constructed. This sign must be reversed in making inferences.

Table 1. Estimated function under various modifications of the Wolffram (W) and Tweeten-Quance (T-Q) models

General Specification	Equation	Model	R^2	A^a	Estimated parameters of		
					X'	X''	D
Actual parameters				3 or 5	5	3	2
Actual relationship specified by Wolffram (equation 6) with a constant 3 added to Y for increasing observations of X and 5 added to Y for decreasing observations of X	1	T−Q	.95	−36.21	6.19	7.07	na
	2	W	1.00	2.26	4.82	−2.68	na
Same as above except that a 0–1 dummy independent variable D was added to account for the different intercepts of the increasing and decreasing observations of X	3	T−Q	.96	−50.00	7.07	6.09	26.89
	4	W	1.00	3.00	5.00	−3.00	2.00

[a] The true constant in equations 1 and 2 is 3 for increasing prices; 5 for decreasing prices. The true constant in equations 3 and 4 is $A=3$ for increasing prices; for decreasing prices it is $A+D=5$.

Table 1], using both the T-Q and W techniques and adding to each the "dummy" variable D, which proved useful in the above example, to allow for different supply constants for increasing and decreasing prices. The resulting equations (5) for the T-Q model and (6) for the W model are disappointing:

$$
\begin{aligned}
Q^t = &-19.78 + \underset{(.0219)}{.0415}\,(P_r/P_p)_d^{t-1} \\
&+ \underset{(.0231)}{.0676}\,(P_r/P_p)_i^{t-1} + \underset{(.0638)}{.9634}\,T + \underset{(.0561)}{.1804}\,Q^{t-1} \\
&+ \underset{(3.504)}{2.622}\,D \\
R^2 = &\ .9967
\end{aligned}
\tag{5}
$$

$$
\begin{aligned}
Q^t = &-10.92 - \underset{(.0226)}{.0654}\,(P_r/P_p)_d^{t-1} \\
&+ \underset{(.0166)}{.0424}\,(P_r/P_p)_i^{t-1} + \underset{(.0744)}{.9958}\,T + \underset{(.0584)}{.2003}\,Q^{t-1} \\
&- \underset{(.5361)}{.3385}\,D \\
R^2 = &\ .9965
\end{aligned}
\tag{6}
$$

The notation d and i refer respectively to decreasing and increasing prices. P_r is prices received by farmers, P_p is prices paid by framers, Q is output, and T is time. Standard errors are in parentheses. The coefficient of the dummy variable D is not significant in either model. Thus, the hypothesis of different supply constants for increasing and decreasing prices is not supported. Adding the dummy variable D did result in a larger coefficient for increasing prices than for decreasing prices in the T-Q model, a change in conformity with fixed asset theory. The original form of (5), excluding D, showed no difference in coefficients. Contrary to economic theory, the coefficient for declining prices in the Wolffram model is larger than the coefficient for increasing prices.

In summary, the Wolffram technique for segmenting variables is superior to ours and should be employed when the analyst has reason to expect that responses differ between segments of an independent variable. We recommend adding a dummy 0–1 variable to his technique to allow a different intercept as well as slope.

In equation 7 in our supply study [1, p. 344], in which we segmented the price variable, no difference was found in the response of output to increasing and decreasing prices—perhaps because our approach appears to be biased toward similar coefficients for the components of the segmented variable. Using other methodologies in the original study, we nevertheless concluded that the supply elasticity was greater for increasing than for decreasing prices.

Application of the Wolffram technique with and without a dummy variable D added no acceptable new information to our original findings; in fact, his approach showed a greater output response to decreasing than to increasing prices. We continue to endorse the final estimates of the supply elasticities given in our earlier study.

TEMPORAL RELATIONSHIPS AMONG FUTURES PRICES: COMMENT

In a recent article in this Journal, Professors Tomek and Gray [1] claim to have found important basic differences in temporal price relationships between futures markets for commodities having continuous inventories and futures markets for commodities lacking such inventories. Examination of their criteria and evidence suggests that they have overstated their case and that the differences are a matter of degree rather than a matter of kind.

Two empirical criteria for contrasting potato futures price movements with corn and soybean futures price movements are employed in the article. One involves the regression of the closing price of the new crop future at expiration on its April 30 price. The other is a revenue variability criterion involving an F test of the difference between the variance of the price of the new crop future on April 30 and the variance of the price of the same future at expiration. Closer examination suggests that neither of these criteria is appropriate.

The most obvious shortcoming shows up in the application of the revenue variability criterion to corn and soybeans. The measures of variability employed are the variances (or standard deviations) of each price about its mean for the entire 17-year period. The resulting variance ratio would be meaningful if it could be assumed that these yearly deviations from the mean were random. However, it is a dubious criterion to use when the deviations are systematically related to other variables.

During the period studied, 1952–1968, the price support level for corn varied between \$1.00 per bushel and \$1.60 per bushel while soybean price supports varied from \$1.85 to \$2.56. Since the support prices were announced each year prior to April 30, it is reasonable to assume that farmers and traders took these into consideration when forming their price expectations on that date. Indeed, futures prices followed support prices rather closely over the period, as can be seen by inserting the support price in the Tomek-Gray Figures 1 and 2.[1] The simple correlations between the respective support prices and the closing futures price on April 30 were .80 for December corn and .91 for November soybeans. Apparently the whole price structure, including producers' expected prices, shifted up and down with the support price over the period for both commodities.

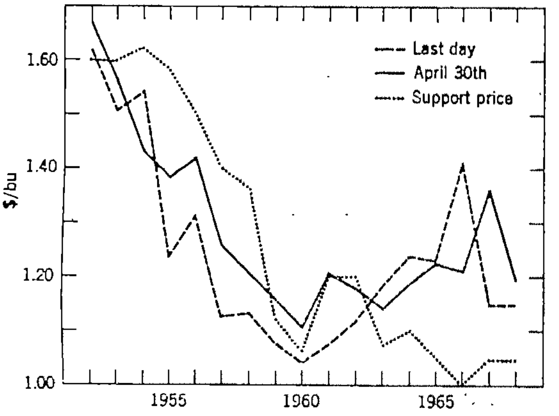

Figure 1. Corn support price to cooperators and closing prices of December corn contract on April 30 and expiration date, 1952–1968

It is obvious that the revenue variability criterion is not meaningful when applied to corn and soybeans in recent years because of the impact of the support programs. Consequently it provides no basis for contrasting these markets with potatoes, and the conclusion that "routine hedging by producers in such markets is unlikely to stabilize their revenues" is unwarranted.[2]

Turning to the regression criterion used in the article, we find results reported that are inconsistent

[1] For 1956–1958 the corn support prices shown in Figure 1 and used in the calculations are the prices applicable to cooperators. The prices used for 1963–1968 do not include support payments to producers.

[2] Results based upon an alternative criterion, involving a more plausible assumption about producers' price expectations, suggest that corn and soybean producers can reduce risk through hedging even while supports are in effect. Suppose, for example, that a producer adopts the support price, plus or minus a constant to take care of location and quality differences, etc., as his expected price at planting time. An appropriate measure of his price risk would be the standard deviation of the difference between the price received and the support price. Measures of the variability of this difference for corn and soybeans over the 1952–1968 period are shown in the table below. The F test for the difference in variance is significant at the 1 percent level for soybeans, providing strong evidence that hedging in the new crop future can reduce price risk for producers who base their price expectations on the support price. For corn the evidence is weaker and the F test is significant at the 25 percent level.

Selected measures of price variability for corn and soybeans, 1952-1968

Price variable	Mean	Standard deviation	F ratio
	cents per bushel		
Difference between the December future and the support for corn			
April 30 close	1.90	14.47	
Last day close	−2.56	18.81	1.69
Difference between the November future and the support for soybeans			
April 30 close	23.57	9.41	
Last day close	31.91	17.58	3.49

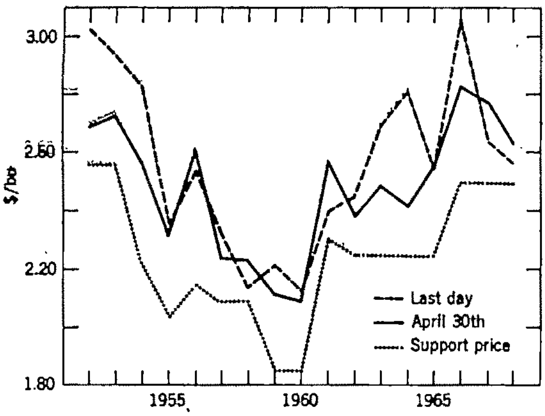

Figure 2. Soybean support price and closing prices of November soybean contract on April 30 and expiration date, 1952–1968

with the competitive nature of futures trading. The regression equations employed provide forecasts in April of the prices of the new crop futures at expiration. If the forecasts were the same as the April 30 prices of the futures, the regression coefficients would be unity and the intercepts would be zero. But any statistically significant differences from these values, such as those reported for potatoes, imply that changes in the new crop futures price can be predicted with success. Such results, if valid, would provide a basis for profitable speculation.[3] Our knowledge of futures trading suggests that any simple analysis that leads directly to the promise of speculative profits deserves to be regarded with supicion. It seems unlikely that a criterion that requires such results for identifying differences can be very useful.

[3] Disregarding trading costs, the predicted profit from holding a long position from April 30 to the expiration of the contract is

$$\hat{\pi} = a + (b - 1)x$$

where a is the intercept, b is the regression coefficient, and x is the April 30 price of the future. We note that when either a is different from zero or b is different from unity, nonzero profits are predicted for some values of x. The decision rule implied for speculators is to hold a long position whenever $\hat{\pi} > 0$ and a short position whenever $\hat{\pi} < 0$.

Table 1. Regression of the closing price at the expiration of the contract on the April 30 price for the November Maine potato future, 1953–1968[a]

Intercept	Slope	$\bar{r}^2$
−2.36 (2.54)	2.06 (1.12)	.14

[a] All data are in dollars per hundredweight. Numbers in parentheses are standard errors.

What then is the explanation for the potato results reported in the article? The answer lies in the data, where we find that the year 1952 was marked by the removal of price controls and exceptionally large price movements. Recalculation of the regression after deleting the observation for 1952 produces the estimates shown in Table 1. These estimates are well within the range that might be expected if the true regression coefficient were unity and the true intercept were zero. Consequently there is no reason to conclude that the forecasting relationship for potatoes is different from that for other commodities in any fundamental sense.[4]

In summary, it appears that the contrast between the continuous inventory commodity futures markets and noninventory commodity markets has been exaggerated by Tomek and Gray. The differences observed between corn and soybeans price movements and potato price movements are due partly to the presence of government price supports for corn and soybeans and partly to an anomaly in the data for potatoes.

RICHARD G. HEIFNER
Economic Research Service, USDA

[4] The $\bar{r}^2$ for potatoes here is small. The possibility remains that the magnitudes of such correlations could be a useful criterion for comparing futures markets. However, some means for taking into account other correlated variables, such as support prices, would be required before such comparisons would be meaningful.

TEMPORAL RELATIONSHIPS AMONG FUTURES PRICES: REPLY

Heifner states that we "exaggerate" the contrast between continuous and discontinuous inventory futures markets and that the differences observed "are due partly to the presence of government price supports for corn and soybeans and partly to an anomaly in the data for potatoes." This reply reviews briefly the conceptual basis of the contrast, clarifies the empirical questions raised by Heifner, and then reaffirms the policy implications of the contrast.

We are not unaware of the price support programs in the United States, but their existence need not obscure the central point of our paper. Changing expectations are, of course, reflected in changes in the constellation of prices, and our article is quite clear on this point [3, p. 375]. In this context, however, commodities with inventories have an advantage over those with discontinuous inventories (whether or not price support programs exist) in the formulation of expectations. Moreover, continuous inventories permit adjustments, to some extent, to changing expectations about supply-demand conditions for the new crop.[1]

Perhaps the best place to begin an attempt to clarify some of the empirical issues is with Figure 4A and 4B in our article [3, p. 377], which evidently do not trouble Mr. Heifner. The underlying logic of our argument is reflected here; and it is surely no exaggeration to say that the May and December corn futures prices are closely related, while the May and November potato futures prices are essentially uncorrelated. These, of course, are daily prices during a month, whereas our analysis stressed year-to-year relationships. But the daily prices indicate that during the month of April estimates of the November potato futures price are independent of the May futures price, whereas estimates of the December corn futures price are strongly dependent upon the current May futures price. This contrast, we repeat, occurs because no potato inventories are carried between crop years, while corn inventories *are* carried and *do* determine the relationship between the May and December futures prices.

The level of free stocks of corn dictates in April of any year whether the May futures price is above or below the December futures price and by how much. In selecting 1969 for our illustration at the time of writing, we happened to choose a year in which the price of the May future in April averaged 2–3 cents higher than the December future because free stocks were relatively tight. Had we selected the prior year, when free stocks were plentiful, the May future would have been shown 6–7 cents below the December future—but still highly correlated, and with prices trending downward instead of upward during April.

Now there is no question but that the price support program for corn, as an example, has a pronounced influence upon the proportion of total stocks that is left free to influence this relationship. In 1963 the corn carryover exceeded 1.3 billion bushels, but less than 80 million bushels were free; whereas in 1967 the carryover was down to 823 million bushels, of which 449 million were free. *But the price support programs have not altered the fact that prices of cash grains and successive futures are linked by inventories* nor the fact that the interplay between inventories and price spreads lends the aspect of self-fulfilling prophecy to grain futures prices which is absent from potato futures prices.

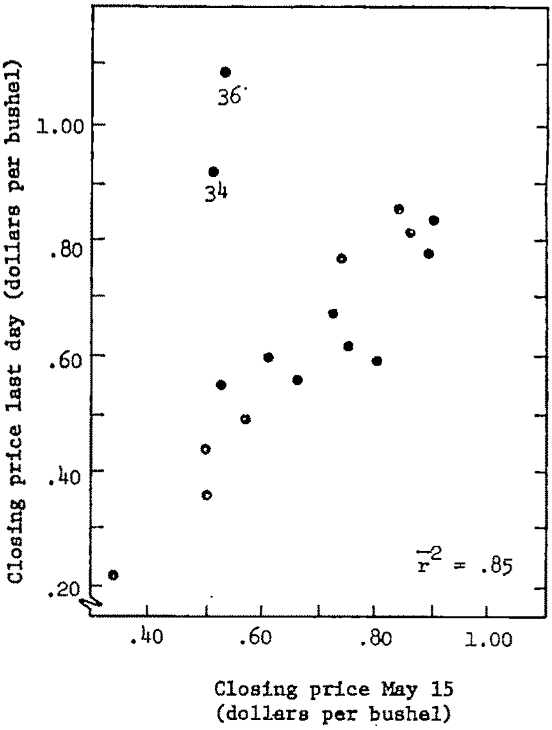

Figure 1. Prices of December corn contract: May 15 and expiration day, 1925–41

Consequently, we find the evidence for the post-World War II period sufficiently persuasive; but evidence from an earlier era (1925–1941), when price supports were not operative, also supports our argument (Figure 1). In this figure the regression line is fitted to all of the observations excepting those shown for 1934 and 1936. The reason for deleting 1934 and 1936 is that these were potato-type years rather than corn-type years, in the sense that the crops were so short that the (small) carryovers could have no substantial influence upon new crop prices.[2] The inventory linkage was overtaxed and virtually broken by these highly abnormal crops, and in this

[1] The constellation of prices for soybeans has been consistently above support levels; i.e., soybean prices have been largely determined by "free market" forces (e.g., see [1]. Now, farmers' planting decisions apparently are influenced by the announced support level [2]; but on April 30 traders have no more information about future soybean production than about potato production, and ex post supply relationships (on which to forecast production) are equally available to traders for all of these crops. In sum, prices for soybeans and potatoes have been largely determined by "free" economic forces and approximately equal (i.e., no) information is available on production; yet the degree of relationship between the April 30 and final closing price differs.

[2] The corn crop typically varied in the range of 2 to 3 billion bushels in the 1925-1941 period. The crop sizes were 1.4 and 1.5 billion bushels in 1934 and 1936, respectively.

Table 1. Estimated linear regressions of the closing prices at the contract expiration on the prices for selected earlier days for the November Maine potato future, 1953–1968[a]

Date	Intercept	Slope	r^2
Feb. 28 (29)	4.64 (2.79)	−.99 (1.19)	.05
April 30[b]	−2.50 (2.54)	2.12 (1.12)	.15
May 15	−3.00 (2.50)	2.32 (1.09)	.24
July 15	.91 (.70)	.62 (.30)	.23
Sept. 15	.31 (.39)	.88 (.17)	.66

[a] All data are in dollars per hundredweight. Numbers in parentheses are standard errors.
[b] This estimate differs slightly from Heifner's (see his Table 1); presumably the data differ somewhat. For 1953–1970 the regression coefficients are essentially unchanged and $r^2 = .21$.

sense, the exceptions prove the rule. It was precisely in the years of extraordinarily small crops, when inventory adjustments were inadequate, that the relationship between the springtime and harvesttime prices was broken. If anything, the relationship is closer (r^2 larger) for this nonprice support period than in recent years.

Heifner goes from floor prices under corn to ceiling prices over potatoes in striving to the conclusion that the differences we observed were due partly to price supports and partly to an anomaly in the potato data. He finds that "the year 1952 was marked by the removal of price controls and exceptionally large price movements." But the facts indicate otherwise. Price ceilings were established on potatoes on January 19, 1952, removed on June 6, 1952, and *never once did the November futures reach or approach the ceilings.* The price of the November future on May 31 before controls were removed was $2.76; on June 15 after controls were removed, $2.74 per hundredweight. It is also well to recall that in 1951, with no ceilings in effect, the November future closed at $2.18 on April 30, $2.00 on June 30, and $3.66 on November 15.[3] Hence, the price ceiling argument is not pertinent.

If this disposes of the alleged cause of the eccentric 1952 observation, it does not dispose of Heifner's

[3] The 1951 and 1952 crop years represent two consecutive years of small potato crops, following discontinuance of price supports with the 1950 crop; and the average U.S. farm price of potatoes in 1952 was the highest since 1919. Thus the cash price for Maine potatoes in November 1952 presumably reflects the prevailing supply-demand conditions for potatoes. Since the 1952 observation does greatly influence the regression coefficients, this perhaps is sufficient justification for dropping that year. Our original justification for including 1952 was that 1951 was the first year of active trading in Maine potatoes but the volume of trading was still quite small. Thus 1952 seemed to be a natural starting point.

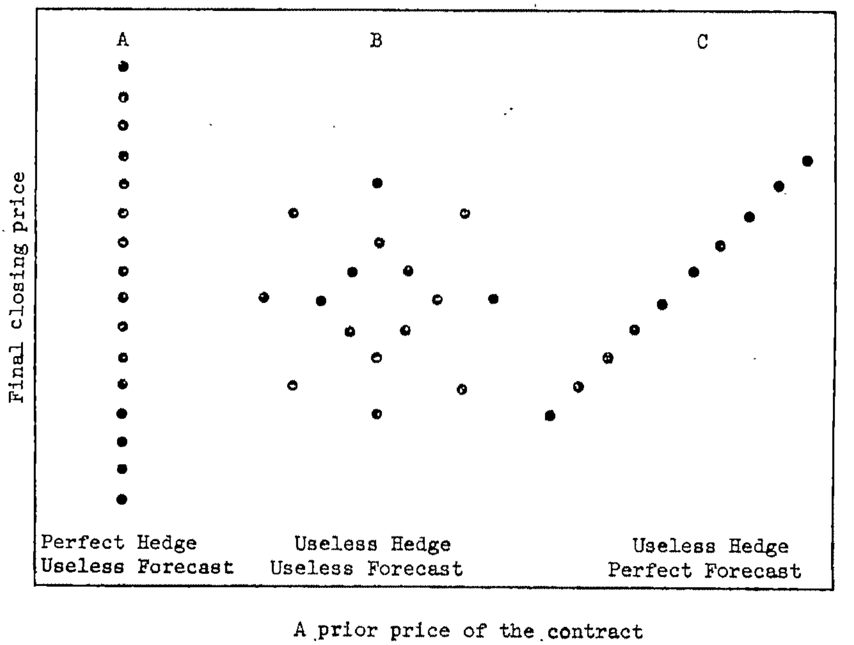

Figure 2. Three hypothetical price relationships between a forecast and realized (final closing) price for a futures contract

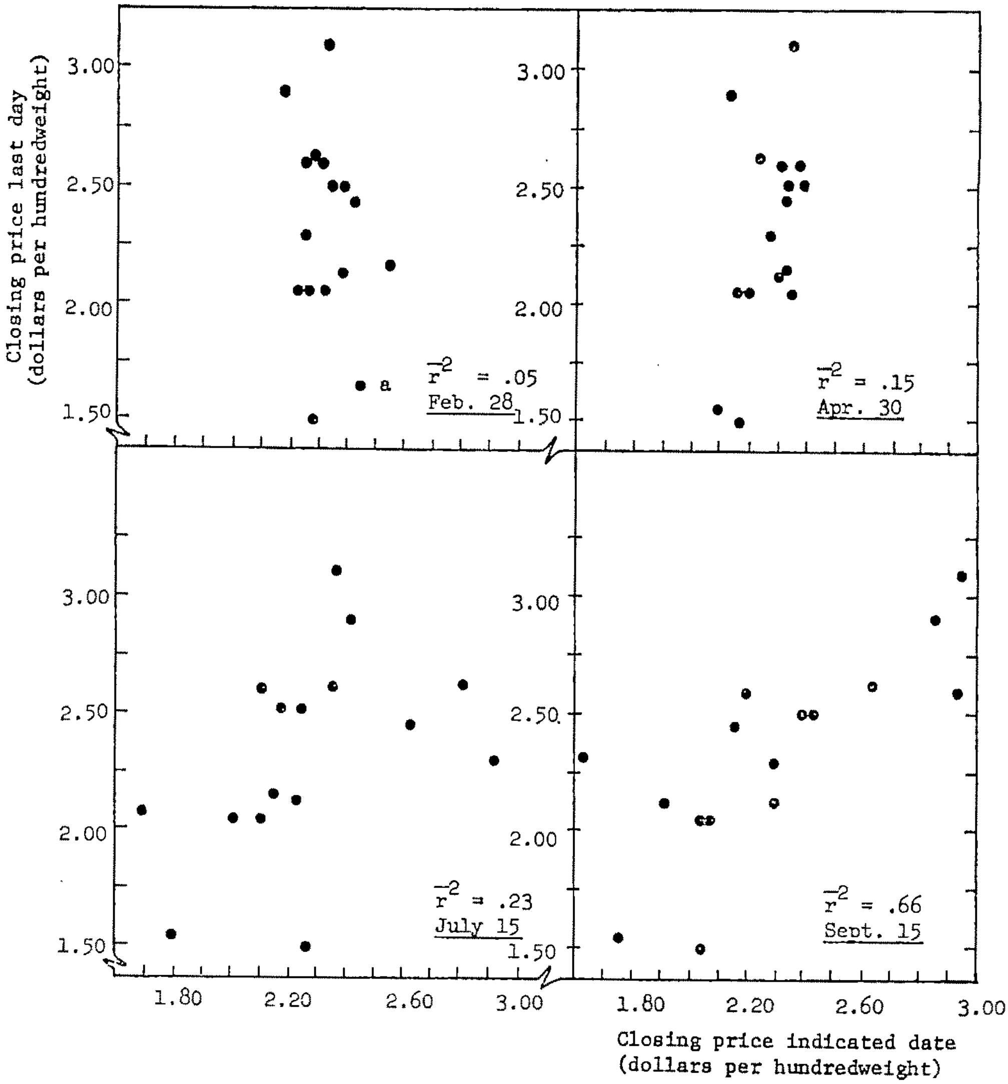

a/ In 1953 the February 28 quotation is for the "old" November contract; for the other dates quotations are for the "new" November contract.

Figure 3. Prices of November Maine potato contract: relationships between prices on selected days and prices on expiration date of contract, 1953–1968

misinterpretation of the consequences of deleting this year. A markedly different equation with a markedly lower r^2 (see Table 1) results from the deletion. But Heifner, in stressing the effect of the 1952 observations on the regression coefficients, misses the point that a forecast at the mean value of past observations provides no basis whatsoever for successful speculation, yet provides a means for reducing year-to-year price variability through hedging. A bad fit, no matter what the slope and intercept, provides a bad basis for speculation; but if the variance of the springtime prices also is near zero, a near-perfect basis for hedging exists. If the variance in the springtime values equals the variance of the realized prices, routine hedging will be useless for reducing annual price variability.[4]

[4] Heifner criticizes the policy implications drawn from the contrasting variance ratios. Two points need to be made in rebuttal. First, economists have recommended routine hedging of production decisions by farmers as an *alternative* stabilization policy to price support programs. Thus, Heifner's comments in footnote 2 about hedging strategies with price supports is irrelevant to the conclusions drawn in our article. Second, the contrasting variances do indeed imply differing levels of stability in response to routine hedging programs, and the reader can easily demonstrate this to his own satisfaction with examples using the available data.

Limiting the consideration of hedging to its role in reducing the year-to-year variability in price (as we did), the relevant relationship between hedging and forecasting is depicted in Figure 2. In part A the observations of the springtime price of the post-harvest future all fall on the mean value of the final price; this makes for the perfect hedge (in the above sense), but of course the forecasts are useless and provide no basis for successful speculation. In B the observations are uncorrelated and the variances of "forecast" and "actual" values are identical; this provides no basis for hedging and also yields a worthless forecast. In C the forecasts are perfect but provide no basis for hedging (again, in the limited sense under consideration). In sum, our argument is that in the spring November potato futures will behave approximately as in A, approaching C as the contract expiration is approached. Lacking the inventory linkage, the market reflects the mean November price until crop information emerges upon which to base better forecasts. As such information emerges, the variance of the forecasts will widen; and if early information is superseded by better information, the midseason (say, July 15) estimates may approach the pattern shown in B before finally resolving into the C pattern late in the season.

We next show, in Figure 3, the succession of actual observations for potatoes for selected dates during each year 1953–1968 (omitting 1952). The February 28 (or 29) observations, as well as examination of those for May 15 (not shown), confirm the impression conveyed by the April 30 observations, namely, that these tend to cluster about the mean value vertically. The results for selected dates (during the years selected by Heifner) are shown in our Table 1. The small $\bar{r}^2$ of the April 30 equation is emphasized by comparison with the February 28 equation; what is obvious is that the early season price estimates are nearly the same every year.[5]

These early season estimates for Maine potatoes are apparently based upon the *mean* of the November price; the April 30 price forecasts do not differ significantly from the forecast that the November (expiration) price will always fall at the mean value.[6] Yet the difference in variances between April 30 and November closing prices is great. Thus, they provide near perfect-hedges and near-useless forecasts. On July 15 the forecasts are also poor, but as the variances of the two series now approach equality July 15 provides a poor hedging date (in the sense of reducing year-to-year variability). Finally, on September 15 the forecasts are good but the hedge would be poor, as the variances of the September and realized prices are nearly the same.

By the same token, we have proposed that the corn estimate, for example, would closely resemble Figure 2C in the spring (e.g., Figure 1) and therefore could improve less throughout the season. Commodities with continuous inventories have significant additional information in the spring. Perhaps these scatter diagrams should have been shown in our original article. In any event, we trust this makes clear that the contrast was not exaggerated and that it was not due to price supports or the removal of price ceilings. The springtime estimates of the fall prices for corn or soybeans display essentially the same year-to-year variability as the final estimates, price supports or no price supports. The springtime estimates of fall potato prices display much lower year-to-year variability than the final estimates, 1952 observation or no 1952 observation.

Stanford University
WILLIAM G. TOMEK
Cornell University

[5] For the 18 years, 1953–1970, the ratio of the variance of the closing price on the expiration day of the November future to the closing price of the same future on April 30 is 17.2.

[6] The average difference between the April 30 price and the November expiration price for potatoes (in absolute terms) is 30.8 cents; the analogous difference between the mean November price and the observed expiration prices is 34.1 cents. The difference in these differences (3.3 cents) is not significantly different from zero. That is to say, the April 30 price of the November future is not a significantly better forecaster of the November price than the mean of past November prices.

ECONOMETRICIANS AND THE DATA GAP: REJOINDER

In submitting my original comment [1] on the title topic, I felt that the subject was an important one which deserved widespread discussion. Accordingly, I worked on that comment, off and on, for a year and a half before submitting it to the then newly appointed Editor. In my letter of transmittal,

I said that "it is not ordinarily possible to find wrong conclusions in an article and then go back and prove that these wrong conclusions have resulted from faulty data. In the usual case, this is just out of the question." And I added that "the burden of proof should be on the authors of these mathematical concoctions," not on their critics.

This letter ended as follows: "Frankly, I would like to see replies to my comment from other prominent agricultural econometricians, not just from the two authors whose article I have criticized. This, however, is your prerogative." The Editor did not accept the suggestion, and a reply [3] was obtained only from the authors. This proved to be question-begging and issue-dodging, which was perhaps to be expected, but it was also a bit self-serving in that an attempt was made to pass the buck back to ERS.

The Editor felt that publication of this initial exchange would bring in so many other comments and criticisms, on one side or the other, that "our problem will be one of rationing rather than soliciting additional responses." Since more than two years have elapsed, with only one comment [2] published, the Editor's statement can now be categorized along with all our other bum forecasts. The conclusion seems inescapable that most members of our profession do not really care very much whether the newer techniques are properly used or not.

The one comment received [2] was a mild and reasonable one which attempted to differentiate between my "generalizations," *not yet refuted by anyone*, and my specific criticisms of the original article, which are *also not yet refuted by anyone*. The comment concluded as follows: "Up to now, the exchange has been less than straightforward and, consequently, disappointing" [2, p. 680]. My agreement was complete.

Next to appear was another reply [4]—to the one comment received. It blandly denied any wrongdoing, without answering any arguments. It asserted, both gratuitously and falsely, that my "generalizations" are "purely one man's opinion." It again denied what I have been told is the case, namely, that strong and early warning was given, orally, as to the unsatisfactory character of the data. It denied *a posteriori* fishing by describing procedures that *constitute a posteriori* fishing. It made another vague reference to an obscure bulletin as providing justification not included in the Journal article. And it implicitly praised its own brevity in an obvious attempt to shove the whole thing permanently under the rug.

Needless to say, this exchange remains as "disappointing" as it has always been. And if members of our profession have nothing further to contribute, the outlook—for resolving this controversy, for solving some of our important problems, and for the future of our profession—is bleak indeed.

Reviews

Bhuleshkar, Ashok V., ed., *Indian Economic Thought and Development*, Jawaharlal Nehru Memorial Volume, London, C. Hurst, 1969, 445 pp. (65 s)

This book is a collection of papers covering such diverse topics as Nehru's brand of socialism, an evaluation of India's economic performance over the first three five-year plan periods, a comparison of Indian and Chinese performance, and a cursory examination of large numbers of theories and policies in relation to development.

If viewed in perspective, namely, that the particular ideology highlighted in the book is not universally accepted by India's theoreticians or practical politicians, the Foreword by Lord Mountbatten, the Introduction by Welingkar, and the three contributions by Mehta, Dantwala, and Dhavamony on Indian economic thought are interesting papers for the student of India's brand of socialism. What Nehru meant when he declared that "socialism is something even more than an economic doctrine, it is a philosophy of life and as such appeals to me," is given an interesting interpretation by Welingkar in the introduction: "He [Nehru] thought it [socialism] was capable of furnishing answers to several questions that troubled his mind. For instance, there are several social evils which are attributed to 'original sin' in Hindu philosophy and which were based on a belief that human destiny is unalterable, a belief which interfered with any rational or scientific view of life. Nehru thought that, in sharp contrast to this, Marxism embodied a scientific approach to the solution of several urgent issues in the nation's economic and political life."

Among the papers on theories and policies relevant to development, the most outstanding and original contribution is contained in I. M. D. Little's paper, "Public Sector Selection in Relation to Indian Development." In my view, if the book contained nothing but the Little paper, it would have been worth publishing. For the serious student of cost-benefit analysis and criteria for project selection who is familiar with Little's recent comprehensive statement of what has become known as the Little-Mirrlees method [1], the paper provides a valuable historical perspective into the development of Little's thoughts. He basically makes a strong argument for the case that a developing country must give judicious attention to the selection of what to produce and what to import in opposition to those who would make us believe that consumption targets are prima facie evidence for the justification of projects. While Little has made several refinements on the basic ideas contained in this early paper in recent years, it still contains the best exposition of his thoughts on the subject.

Most of the papers in Part II, Agriculture and Development, belong unfortunately to the category of papers in this collection not worthy of a busy reader's time. Many contain a curious mixture of ideological argumentation and empirical analysis, neither of which appears to be current to an understanding of what is happening in India today. Practically all are restricted to describing and interpreting events prior to 1965. The performance and problems of Indian agriculture have since been importantly affected by years of unusually severe and prolonged drought and more recently by the green revolution.

Among the papers in Part IV, Monetary Policy and Economic Development, and Part V, Other Allied Topics in Relation to Development, the more outstanding, although also partially outdated, are those by Bhuleshkar, "Devaluation of the Indian Rupee: A Step in the Right Direction"; by W. B. Reddaway, "The Importance of External Assistance and Self-Help in Indian Development"; and by Ursula K. Hicks, "Educational Expansion in Low Income Countries with Special Reference to India."

Bressler, Raymond G., Jr., and Richard A. King, *Markets, Prices, and Interregional Trade*, New York, John Wiley & Sons, Inc., 1970, xviii + 426 pp. ($13.95)

This is a good book; it is a worthy valedictory from the late Professor Bressler. The textbook that he and

Professor King present to us is an example of that complementarity between research and teaching that many of us seek. Concerned as it is with applied price theory in a spatial setting, the work is interwoven with the results of two decades of research (by the authors and others) on problems of pricing in spatial markets and interregional competition. Indeed, the book can be regarded as a logical outgrowth of this research program.

There are five parts. Parts I-III, or possibly IV, are intended for undergraduates; parts IV and V for graduates. Part I opens with a brief history of U. S. economic development and then describes the U. S. economy as it now exists. The authors' intention here is to place the concepts of regional specialization and interregional trade in their historical context: These are not merely abstractions of economic theory; they have in fact occurred.

Part II develops the theory of price determination in a spatial market. Examples are drawn from research, and the use of transportation and reactive programming models are illustrated by sample problems. The figures in this part of the book are especially well done, with many maps and blueprint-style drawings showing both cross-sectional and plan views of three-dimensional relationships. These should prove very useful to students.

The relationships of time and product form with market price are taken up in part III. The exposition is presented from the point of view of a perfectly competitive firm with perfect knowledge of current alternatives and future events. The relationship of price with time is thus reduced to a matter of storage costs. The authors promise (on p. 211) to reconsider their assumption of perfect foreknowledge but do not seem to have done so. Because uncertainty about the future is practically inherent in economic events, the treatment of time seems inadequate.

The interactions of time, form, and space in determining market price are illustrated by seasonal fluctuations in milk production and the resultant changes in fluid milk, cream, and manufacturing milk prices and production zones. The subjects of price discrimination and nonprice factors affecting markets are also taken up in part III. Students will undoubtedly be pleased with the account of Rhode Island's "Pink Milk Caper," included in the discussion of nonprice factors.

Parts IV and V present an evolving picture of the theory of trade and regional specialization together with, in part V, a review of methodological approaches to research in this area. Prior knowledge of operations research techniques is presumed, for much of the exposition is in linear programming terms. Part IV starts with the classic Edgeworth box analysis of the exchange of stocks between two individuals or regions. The analysis is gradually generalized to allow supply from production rather than stocks and investigates the implications of differential production functions for regional specialization and trade. The question of land use is taken up in part V, demonstrating the law of comparative advantage with respect to land and its resultant implications for specialized land use and interregional trade. As indicated, the main thrust of part V lies in its discussion of methodological approaches to problems of location analysis and spatial equilibrium research.

If the book has a serious shortcoming, it is the short shrift given the theory of demand. This is perhaps not too serious in the undergraduate portion, where the focus is on the perfectly competitive firm and demand can be taken as given. It is less satisfactory in the graduate portion, where the focus is on regions. The exposition of trade theory in part IV is prefaced by a brief discussion of the theory of consumers' choice, but nothing is said about the effect of income change. Demand functions containing income terms are encountered in part V as specifications in a general equilibrium model, but nothing is said about what effect they might have on the functions or on model solutions. The terms "income effect" and "income elasticity" apparently never appear in the book.

Of course no book can cover everything, and the excellent treatment of spatial economics that we are afforded here more than makes up for the omissions. Students using this text should be able to get a thorough grounding in the principles of spatial economics, a topic that has been neglected in most economics texts but is vital to an understanding of many aspects of agricultural production and marketing.

BARRY W. BOBST
University of Kentucky

Duckham, A. N., and C. B. Masefield, *Farming Systems of the World*, New York, Praeger Publishers, 1970, XVIII + 542 pp. ($21.50)

An agriculturist is a kind of generalist with practical leanings who is now rare in the United States. It is therefore refreshing to find a book by two English agriculturists on the subject of comparative systems of agriculture. This one is built on the solid foundation of 13 years of lectures at the University of Reading, England, and first-hand experience in the countries discussed. The senior author, A. N. Duckham, is known to many older American agricultural economists as an engaging person who served as British agricultural attache in the United States some 20 years ago. The other author, G. B. Masefield, was for many years in the British Colonial Agriculture Service, mainly in the tropics.

The authors' objectives, as indicated in their introduction, were three: (1) to produce a textbook on comparative agriculture for university use; (2) to provide a reference work for agriculturists, researchers, and administrators; and (3) to attempt, for temperate countries, to construct models poten-

tially capable of quantification that would explain location, input intensity, and food output of farming systems.

They indicate (cryptically) that they hope to bridge the gaps between tropical agriculturists, temperate agriculturists, and economists. This seems to suspend economists in a limbo between temperature zones, but this is not what they mean. What they have really done is to provide a useful reference book with a broad coverage on a once-over-lightly basis of what used to be termed physical and economic geography and what, with some important additions, is currently glorified as ecology. They do not attempt to cover the whole world but instead have a representative selection of countries (other than the communist nations for which good information is scanty) in both the temperate and tropical zones.

An ingenious "transect" device is used to provide a running profile of farms and farming systems as one passes across each country in one or more straight lines. Detailed information is presented for 42 sample farms and for a much larger number of farming systems around the world. Tables, charts, and pictures are used in abundance.

Americans will question some of what is said about the United States. For example, the statements about trends toward large-scale farms and toward contract farming seem overdrawn.

British terms will also need translation for some readers. Not everyone will recognize that lucerne, fodder, lorry, sward, pulses, groundnuts, and influents mean simply alfalfa, concentrate feeds, truck, grass, beans and peas, peanuts, and causal factors. But these are relatively small matters. A more serious fault is that some of the many excellent charts and tables are too full of information and are difficult to unravel.

Agricultural economists as well as agricultural ecologists and administrators will find this a useful reference on comparative systems of agriculture and a convenient place to get first impressions of the agriculture of the selected temperate and tropical countries. It will also be useful for supplementary reading in university courses. The attempt to suggest a way to build models for potential programming is interesting but less successful because of the complexity of the problem.

Grunwald, Joseph, and Philip Musgrove, *Natural Resources in Latin American Development*, Baltimore, The Johns Hopkins Press, 1969, xvii + 493 pp. ($20.00)

One of the serious problems of Latin American development policy is the role of primary products. On the one hand, following the leadership of Paul Prebisch, interest has been centered on developing manufactures. On the other, progress has been extremely limited in exporting manufactures, so that export success to date is almost synonymous with primary products exports. Also, success in obtaining increases in production and exports of primary products may be useful in development of manufacturing capacity and the essential imports of raw materials and component parts.

The purpose of the book is an assessment of the contribution of the natural resource sector to the economic development of Latin America. For four centuries primary products have dominated production and exports of the region, with raw materials constituting 95 percent of exports until the last decade. Nevertheless, the transformation of the economy that is represented by industrialization has made considerable progress since 1930, when the worldwide depression and the great fall in demand for raw materials spurred diversification. Between 1929 and 1960, the combined industrial output in the five major countries grew twice as fast as total gross domestic product. Growth was especially marked between 1929 and 1950, although there was little or no increase of exports by most countries as import substitution was emphasized. Throughout the period, there has been little development of manufacturing for export.

The next phase of Latin American development, the authors say, must include such a growth in manufacturing exports or the integration of the industrial and export sectors to a greater degree than at present. Perhaps, this may be achieved through the economic integration of the region aided by evolution of the present Latin American Free Trade Area (LAFTA) and other trading groups of states. The resource sector may ultimately yield to industry its predominant role in earning foreign exchange. The result would be an economy in which the primary sector had ceased to be a sector apart and had become fully integrated with the rest of the Latin American economy.

Yet the shift from dependence on raw materials for foreign exchange earnings faces tremendous difficulties. Latin American industrialization has not yet proceeded far enough to become independent of foreign supplies of machinery, equipment, replacement parts, and components. Accelerated industrialization will therefore require increased imports of the needed materials for domestic production despite the declining needs for imports of finished consumer goods. In addition, Latin American industrial products are not yet able to compete effectively in the world market. Without receiving preferential treatment in developed country markets, manufactured exports cannot be relied upon in the foreseeable future to earn the foreign exchange needed for economic development. The role of foreign capital is being limited, partly because of the memory of past abuses and partly because of growing national concern about foreign control.

The problems with ownership of minerals resources are especially troublesome. They are complicated by

the exhaustibility problem, i.e., the fear that resources may be exploited mostly for the benefit of foreigners.

Agriculture is less troubled by foreign control, despite conspicuous exceptions. And the danger of exhaustion of resources is minimal. The chief problem is with the supply of temperate zone crops where the expansion of domestic demand has been greatest. Most of the increase in agricultural output in the past has been derived from an expansion in area, with limited increase in yields. In most circumstances such expansion provides little increase in output per person employed and little or no reduction in costs. The good, readily accessible land is already being used and the vast, untouched hinterlands may not be of immediate value for agriculture under the present state of technology.

"Basic changes in the structure of production will be necessary before significant progress in agriculture is possible. This sector has been the weakest link in the chain of Latin American development, and in many countries agricultural production has lagged seriously behind population growth in the post World War II period" (p. 40).

The book begins with an historical survey of the development of the region, with emphasis upon the effect of the shrinkage in world markets for primary products during the great depression and World War II upon the decision and need to industrialize. Then a chapter on "Major Issues and Problems" is an excellent analysis of the many-sided relation of resource industries to economic development and progress, recounting Latin America's experience and prospects. The responsibility of developed countries in lowering barriers to manufacturing imports from Latin America is essential for the transformation and industrial development of the region. There follows a statistical summary, by products, of resource industries and a long appendix, by countries, that is conveniently arranged for reference. The final section, comprising two-thirds of the book, has separate chapters on each of the 15 major commodities produced by the resource industries of the region. The products include six minerals, seven farm products, forestry, and fisheries. The farm products are coffee, cocoa, sugar, bananas, wheat, beef, and cotton.

The work is intended for use in university courses as well as for development economists who need an introduction to the various countries and the specific products of the natural resources sector. Its incisive treatment and convenient arrangement will make the book valuable to each group.

L. JAY ATKINSON
Economic Research Service, USDA

Hadwiger, Don F., *Federal Wheat Commodity Programs,* Ames, The Iowa State University Press, 1970, xi + 407 pp. ($10.50)

The stated objective of the author is to present a history of federal policy relating to wheat in the 20th century. He seeks to answer three questions: Where did the policy come from? What was the policy? What were its effects? Hadwiger attempts to do this by interweaving political and economic analyses of wheat policy. The approach is first to review in sweeping summary form domestic policies from pre-World War I to the end of the Freeman regime (chapter 2). Next the reader is treated to a more lengthy review of export policies over the same period (chapter 3). Thus, after the first 80 pages, the reader has been the gamut from 1914 to 1968 twice by means of a somewhat artificial attempt to separate domestic from export policy. At this point the reader might anticipate similar 60-year sweeps on other more detailed aspects of policy. But such is not to be. Hadwiger then begins to treat chronologically the two price schemes of the 1920's (chapter 4), the Agricultural Marketing Act of 1929 (chapter 5), and the 1933–1935 life of the first AAA (chapter 6). Then we jump to the 1938 AAA in chapter 7, and the reader who knows something about wheat policy wonders what happened to the Soil Conservation and Domestic Allotment Act of 1936. Chapter 8 next jumps to the Benson period, 1953–1960, and one wonders this time what happened to postwar policy, the Brannan Plan, and the Agricultural Acts of 1948 and 1949. Then, as if the author also began to wonder, these turn up in a 10-page insert in the middle of chapter 8. In chapter 9 the author leads us to soil conservation measures, which begin with the missing Soils Conservation and Domestic Allotment Act and finishes with the soil bank legislation of 1956. Hadwiger then treats the Freeman programs of the 1960's in considerable detail and with much insight (chapter 10). The remaining chapters deal with stocks and the CCC (chapter 11), distribution of producer benefits (chapter 12), food aid (chapter 13), and some conclusions.

After having read the book, the reviewer wondered whether a different organizational format might not have made the book more readable. Hadwiger has done a scholarly job of research by including, somewhere in the book, a great deal of well-documented information about wheat policy. His prose is also very readable; but every so often one pauses to ask, "Why am I here and where am I going?" Perhaps the organizational format is more confusing to one who knows a little about wheat policy than to one who knows nothing. But this reviewer certainly would have preferred a chronological history. American farm policy, and wheat policy in particular, evolved as a product of ever-changing times, with the methods of approach very much a product of the times and interrelationships with other commodities.

The approach of intertwining political and economic factors into a politico-economic study of policy has much merit. Particularly in dealing with the Freeman area, Hadwiger demonstrates that the interaction of farm groups, Congress, and the Executive Branch generally yields compromises that

don't look much like what any particular group wanted. Also emerging are the different effects of doctrinaire (Benson) versus pragmatic (Freeman) approaches to wheat policy. These differences occur both with respect to the conceptual approach and the administration of programs. Clearly, the political characteristics of the men involved interact, sometimes in strange ways, with the economic issues involved.

Hadwiger's book is well written, and it contains a wealth of information on wheat policy never before assembled in one book. Its weakness is that unless one knows a great deal about wheat policy the information is difficult to find. To the uninitiated reader, the book unfortunately may be more confusing than enlightening.

ALEX F. MCCALLA
University of California at Davis

Hartman, L. M., and Don Seastone, *Water Transfers: Economic Efficiency and Alternative Institutions*, Baltimore, The Johns Hopkins Press for Resources for the Future, 1970, xiii + 127 pp. ($5.75)

This little book has more in it than its size would indicate. It is a simple and concise presentation of the conceptual structure for analysis of the economics of water transfer and the economic changes induced by alteration of the resource base in any basic economic sector. The presentation is largely verbal, simply written, and eschews symbolic presentation except at a few points where symbolization simplifies rather than clouds understanding. It avoid mathematical formalization entirely except in some conceptual explanations of empirical analyses.

Its concise presentation, however, makes rapid reading impossible. With the exceptions of Chapter IV–VI, which are empirical descriptions of the structure and behavior of water organizations in Colorado and New Mexico, not only is every paragraph and every sentence important but every phrase within each sentence, often every word, is essential to the argument and must be read and grasped by the reader in order to follow the logic of the argument.

Chapter I (5 pages) sets the problem in the relative immobility of water resources as between uses and areas of use stemming from the physical interdependencies of water uses which preclude simple property-right systems for water. The authors formulate the conceptual structure and to a lesser degree test it empirically, for analyzing the economic efficiency with which the institutional system peculiar to water affects the allocation of water among uses and areas. Two basic types of institutions are analyzed "in terms of the efficiency of their allocative function: the law and its implementing procedure; and the rules governing the internal and external operation of various kinds of collectives."

They begin, in Chapter II (9 pages), by considering "the allocation of water within a single basin from an atomistic decision-making point of view." The question posed "concerns the legal procedures for transfer of ownership rights and how these procedures operate in an efficiency sense."

The problem emerges from the technological externalities stemming from return flow to the stream of diverted water that is not consumptively used which is then available for re-use by others "below" in the system. A technological external diseconomy arises when some or all of one or more upstream users' water is transferred out of part or all of the system, thus reducing the volume or quality, or both, of the return flows available to all users below the previous diversion points of the transferred waters. The aggregate MVP of a unit of upstream diversion is made up of the MVP generated directly in that diversion *plus* the sum of all MVP's generated in each successive use of the progressively diminishing return flows as the unconsumed portion of the initial diversion moves down through the system. Present western water laws recognize this interrelatedness in water supplies by protecting return flow users' rights when a transfer occurs that changes point of diversion or type of use by permitting transfer only of that portion of the right that has historically been consumptively used, permitting the historic return flow to continue to flow undisturbed into the system.

Chapter III (11 pages plus 6 pages of appendix) then examines the transfer process under the appropriation doctrine of water rights as it operates in Colorado and New Mexico, assessing its performance against the criterion of economic efficiency. The authors find that "obstacles to transfers do not inhere so much in existing laws as in the uncertainties associated with the physical hydrologic system and the effects accompanying the transaction and that these uncertainties are affected by the procedures through which factual evidence is generated and evaluated." Hence, not only is market-like transfer discouraged by restriction of the transferable right to the historic consumptive portion thereof but transfer is further discouraged by the uncertainties surrounding how the historic consumptive use fraction will be determined and hence how big it may be held to be.

Chapters IV–VI (28 pages, including 3 pages of appendices) begin by pointing out that transferability of water, which appears to be severely restrained by water rights law and the administrative and judicial processes established to oversee it, is, particularly within a specified use such as agriculture, "more responsive than an analysis of the judicial process of water transfer in Colorado suggests" (as analyzed in the preceding Chapter III). The authors find the institutional circumstance in Colorado that relaxes this apparent restraining influence of water law and its administration in "the development of a set of water organizations, one result of which has been to circumvent some of the rigidities imposed by legal restraint." They then describe the organization

and behavior of mutual ditch companies in Colorado (Chapter IV), the Northern Colorado Water Conservancy District (Chapter V), and the Southeastern Colorado Water Conservancy District (Chapter VI) relative to the apparent loosening of the legal restraints on transfer.

These chapters are brief but cogent descriptions of the differing organizational powers and internal policies of these districts affecting the degree to which they relax in practice the apparently built-in legal restraints on water transfer. In the concluding chapter (IX), relative to the analysis of these organizations, the authors point out that the existence of these districts in Colorado, each having different internal rules affecting internal allocations of water, "suggests that organizations with desirable economic features do not spontaneously come into existence." The contrast between them "points up the need for informed guidance in district formation, i.e., in institutional design." However, they hypothesize that "in situations where some people are made better off and some worse off from a rule change, the change may not take place because of uncertainties in predicting consequences and also because there is no procedure for compensating the losers." The "uncertainties in predicting consequences" derive from our lack of knowledge about the behavior of the hydrologic system; the lack of a "procedure for compensating the losers" refers us back to water law as the source of that difficulty.

A relevant criticism here is that one cannot generalize to all appropriation doctrine states the authors' analysis of the relaxing role of water organizations in Colorado. In Arizona, for example, no such organizations having such relaxing powers exist. In fact, in Arizona, the law as well as Federal reclamation policy severely restrains if it doesn't wholly prevent transferability, not only of historic "direct flow" rights but also of "stored and developed" water rights which are nominally held in their aggregate by the district.

Furthermore, the Hartman-Seastone treatment of technical externalities and organizational powers relative to water transferability relates explicitly only to stream or stream-like *flowing* water. In states like Arizona and others where groundwater of a stock resource type is an important element in the water use picture, frequently exploited in conjunction with surface flows, the analytical problem, though similar in many ways to stream-flow analysis, exhibits complexities and differences in law and water administration sufficient to make it almost a different problem. In these situations the return-flow, hydrologic-system knowledge is far less well-known and more complex, and the institutional structure for coping with it is generally far less well-defined in law and in organizational existence and operating policy. Thus, there is another hazard in generalizing this study's Colorado findings to other situations in other states.

Chapters VII and VIII shift the discussion and analysis to a different problem altogether, although it may be related to the technical externality problem treated in preceding chapters. In the preceding chapters the analysis considers only the economics of the *direct* effects on water users of a water transfer as the transfer and its effects might be modified by organizational behavior. In Chapters VII and VIII, the economic or "market" interdependencies (externalities) that flow *indirectly* from the initiating direct effects on water-using firms are considered.

Chapter VII (22 pages, including 4 pages of appendix) sets up the conceptual structure for the analysis of market externality effects stemming from the direct water-user consequences of water transfers. The authors conceptualize a three-region model that encompasses the national economy: (A) the water "exporting" area (region), (B) the water "importing" area (region), and (C) the "rest of the world" (national economy). They then assume a one-way transfer of an incremental quantity of water from area (region) A to area (region) B and hypothesize the induced flows of productive (nonwater) factors—labor and capital funds and facilities—between and among these areas (regions). In the rest of the chapter they conceptualize the model appropriate for analysis of the induced economic effects of water transfer under conditions that deviate from the idealized competitive model.

They find four different kinds of interdependencies and proceed to identify them specifically and to analyze their effects: "(1) a household income consumption multiplier effect; (2) a business multiplier effect on suppliers of production inputs and related sectors; (3) a cost-increasing effect on firms processing output from the water-using activity; and (4) an accumulative effect on the public sector through loss of tax revenues and reduction in use of public facilities." They then proceed to conceptualize each of these in turn.

They conclude that "consideration of income interdependency effects can be most expeditiously taken into account in the planning stages when the agency is deciding on alternative sources of supply ... the planning group can calculate the income effects of buying water from existing uses to compare with that of bringing in more distant supply sources. In arriving at a cost for buying out an existing use, the rate of withdrawal as it affects labor and capital mobility and the planning time necessary for recovery of capital expenditures is of critical importance."

Chapter VIII (25 pages including 10 pages of appendix) carries through an empirical estimate of negative income effects from water transfer from the standpoint of the exporting or selling region. It illustrates the process of giving empirical content to the conceptual formulation of the preceding chapter. The Imperial Valley in Southern California is the case study chosen because of its proximity to the rapidly growing urban population of the Southern

California coast and the availability of pertinent data.

As one would expect, the empirical study is not as neat and tidy nor as sharp and elegant as the conceptual analyses of preceding chapters. Though the analysis is phrased in terms of the agricultural economy of the Imperial Valley and though some of the quantifications used are of empirical origin, Chapter VIII turns out to be in fact but little more than an illustration and explanation of the use of an input-output model to derive relevant multipliers and the use of the multipliers to derive aggregate income effects stemming from an induced exogenous change.

As an illustration, the chapter is all right as far as it goes. The danger is that unwary, biased, or unsophisticated readers may take the chapter's analysis at face value which, if they do, will lead to much mischief concerning interpretation of the social cost of water transfers from already established irrigation areas. Unfortunately, the authors abet such unwary interpretations by saying, "The order of magnitude of the above estimates [$295 per acre-foot] calls into question the desirability of large block withdrawals of water from developed agricultural areas." No such statement is warranted by the analyses given in Chapter VIII or elsewhere in the report. The multipliers from which this water value is derived are restricted to the Imperial Valley (area A of their conceptual model). Without estimates of the orders of magnitude of the value of the transferred water to affected area B (the receiving area) and to area C as well, no such statement is warrantable.

Furthermore, plausible alteration of some of their key assumptions and some of their empirical manipulations, as well as inclusion in the analysis of some elements of their conceptual model left out of their empirical calculations, materially affects the order of magnitude of even their own estimate of the value of the transferred water to area A.

The many questions concerning the analyses of this chapter that must be considered and resolved in order to guard against the dangers of unwary reading and to make it a more adequate empirical estimate of the order of magnitude of the aggregate costs of water transfer require more space than this review affords.

This little book is a simple but excellent presentation of the conceptual structure for economic analysis of water transfers. The empirical descriptions of the structure and performance of water organizations relative to economic efficiency of such transfers are also pertinent and suggestive, although they are by no means the last word on that subject. The illustrative empirical implementation of the model is the work's chief weakness. This reviewer wishes the authors had left it out entirely or had developed it more cogently and completely.

M. M. KELSO
University of Arizona

Idyll, C. P., *The Sea Against Hunger*, New York, Thomas Y. Crowell Company, 1970, xxi + 221 pp. ($7.95)

Most discussions of present and prospective world food problems include only a short passage on the possibilities of expanding the harvest of food from the sea. Those who would like to know more about the subject may be interested in this book, which was written by a marine biologist. It presents a detailed and systematic examination of the various possibilities for increasing the oceans' food production.

The basic premise is that despite the green revolution land farming will continue to have difficulty in providing man's food needs, and alternative food sources are urgently needed. Although the sea presently contributes only a small part of the world food supply, in the range of 1 to 3 percent of total human calory consumption, fish landings have increased rapidly in the last decade. Also, the qualitative contribution is much more impressive than the quantitative one, as fish supplied 13 percent of animal protein for human consumption in 1960, the only year for which an estimate was given. Since the sea covers 71 percent of the earth's surface, and the same basic food production principles apply as on land, its promise as a source of food demands careful investigation.

Aquaculture, or farming the sea, seems a logical step forward in increasing marine food production. However, husbandry of sea animals involves many unknowns and complexities. Technical problems and the management problem caused by unlimited access in national and international waters will preclude efforts in the bulk of the ocean areas and restrict efforts to the limited shallow-water coastal areas. The author feels that most aquacultural development in the near future will involve expensive products for high-income nations rather than food for poor people in developing nations.

Discussed and then rejected as basically infeasible for a variety of reasons are the harvesting of plankton, the use of seaweeds, and the transplantation of useful species into areas where they do not occur naturally.

Some areas of the sea, such as the Atlantic Ocean off the west coast of Africa and the Indian Ocean, could support larger fishing efforts; but many of the most productive areas are already heavily fished. If more men would be willing to eat largely unexploited species such as squids, sharks, and sand lances, these could be harvested as an addition to the food supply. The author is particularly enthusiastic about the potential for using presently undesirable species either in fish protein concentrate, a tasteless, odorless flour which can serve as a protein additive to more familiar human foods such as breads and soups, or in fish meal which is used in animal feeds. The discussion of the possible yield from more intensive

or extensive fishing of the traditional type is clouded by considerable uncertainty about the actual sizes of stocks, future demands for nontraditional products, future changes in harvesting technology, and developments in legal-political arrangements for the use of the sea.

The conclusion is conservative. Although food material is manufactured in the sea in very great quantities, the potential is not likely to be realized because of the numerous biological, social, economic, political and technical barriers. "If we concede imperfection of man and the reality of nature, it is probably realistic to hope that the sea will some day produce 200 to 250 million tons of usable food—four to five times the present yield. To the extent that man becomes more rational in his behavior and that he sharpens his understanding of the complexities of the ocean and his skills in fishing techniques and management, larger harvests will be possible: perhaps 400 million tons without stretching credibility —one billion as a more remote possibility" (p. 203). Thus, although he advocates increased efforts in this area, Idyll does not feel that the sea is likely to offer a significant solution to human food problems.

This is a book written for intelligent laymen. It was interesting to read, and a number of photographs added to its appeal. However, some errors, inconsistencies, and editorial weaknesses were noted. The charts and tables, apparently unmodified in form from the original sources, were not always appropriate and were sometimes located several pages away from the relevant discussion in the text. I was left with the impression that the author gathered statistics from the most convenient sources and did not always further check to determine whether the different statistics were consistent.

There are few comprehensive books on this subject. For a balanced introduction to the full set of considerations relevant to the development of marine fisheries, I recommend that the reader supplement Idyll's book with Christy and Scott's *Common Wealth in Ocean Fisheries* [1], which was previously reviewed in this Journal (50:775–777, Aug. 1968). Christy and Scott give a more thorough discussion of economic, legal, and political issues. Critical aspects of fisheries management are the short-run and long-run economic inefficiency and conservation problems that result from resources being international common property. Idyll does not ignore economic considerations, but, as would be expected from a biologist, his treatment is quite simplistic. He is also obviously a pragmatist who rather resignedly feels that extension of present bilateral and multilateral agreements among nations is about all that can be expected in the way of improved human arrangements for management of marine fisheries. The chief values of Idyll's book are its wealth of insights into the nature of sea animals and its fascinating albeit discouraging compilation of the many problems encountered in attempting to harvest food from the sea.

There is a disturbing postscript to this review. As I write it, the newspapers are reporting that unacceptably high mercury levels have been found in tuna, swordfish, and other fish and shellfish. The full extent of mercury contamination and other types of marine fish pollution is not known, but it may be pervasive. Further studies and explanations are needed and will be forthcoming. To some extent, it is hoped to a small degree only, this book may already be obsolete.

[1] CHRISTY, FRANCIS T. JR., AND ANTHONY SCOTT, *The Common Wealth in Ocean Fisheries*, Baltimore, The Johns Hopkins Press for Resources for the Future, Inc., 1965.

Johnson, Glenn L., O. J. Scoville, George K. Dike, and Carl K. Eicher, *Strategies and Recommendations for Nigerian Rural Development, 1969/1985*, Consortium for the Study of Nigerian Rural Development, East Lansing, University of Michigan, 1969, ii + 158 pp. Price unknown. Paper.

This report to the Nigerian Government represents the capstone volume of 45 studies and working papers of some 40 individuals working over a three-year period in a four-university consortium financed by AID. Johnson and Eicher had earlier been the first and second directors (1962–1966) of the AID-financed Economic Development Institute at Enugu, which was primarily concerned with research on agriculture in Eastern Nigeria. This study thus represents the fruit of a large research personnel input and some four to five million dollars.

Nine chapters cover a description of the agriculture sector, trends since 1950, crucial policy issues, alternative agricultural strategies, recommended production campaigns, institutional support, and financial and manpower requirements. Policy measures, output projections, costs, and administrative arrangements are spelled out in admirable detail. The writing is of excellent quality throughout. Each chapter is self-contained and there is a long introductory summary. These features should make the report quite effective as a working manual; they also mean that there is a good deal of repetition for anyone who reads cover to cover.

Chapter 2 provides the most satisfying overview of the Nigerian agricultural economy that this reviewer has encountered. Ecological zones, cultivation regimes, the developmental sequence in land tenure arrangements, the functioning of product and factor markets, and the lagged nature of supply responses

are all described with exactitude and economy. Perhaps the most interesting feature of Nigerian peasant agriculture, and one which receives central attention in the study, is the dichotomy in genetic technology between domestic food crops and primary exports. The latter—palm produce, cocoa, groundnuts, cotton—are based on comparatively high-yielding varieties that have benefited from considerable external borrowing and internal research; the problem here has been the various forms of commodity taxation that have tended to repress Nigeria's comparative advantage and thereby aggregate export volume. On the other hand, the unimproved plant varieties of cassava, yam, millet, maize, and guinea corn result in very high-priced domestic proteins and starches. The authors' principal policy correctives for releasing these constraints on agricultural development include removal of export taxes, biological research, extension, and the discontinuance of unsuccessful public enterprises such as farm settlements and plantations.

As a policy document this report should exert a beneficial influence. Given the propensities of Nigerian policy makers, the case against export taxation cannot be made too often. The persuasive counsels for close regional cooperation in the design and administration of agriculture policy are very much to the point in the face of current trends of autonomy for the twelve states. The emphasis on biological research and extension as against glamorous, large-scale directly productive public enterprise is also a useful counter to the strong political attraction toward the latter. Finally, the report contains a fully worked out program which lends itself to direct implementation.

One can, however, question a few of the authors' specific conclusions. The recommendations to expand production of kenaf and sugar did not consider the much cheaper import alternative. The positive evaluation of latex rubber possibilities made no mention of the unsuccessful project in this area in the mid-1950's. The argument that "investment of land, labor, and capital has been pushed beyond privately profitable margins at prices now paid to farmers" (p. 4) is not completely clear. Marginal product is low but no lower than in the urban sector's unemployment-camouflaging activities of small industry, trade, and personal services. Similarly, with the exception of palm oil, it is difficult to show that substantial repression of any export commodity has actually occurred during the last decade; the danger, though, is a very real one.

The reviewer's major criticism of the consortium project is the comparatively little solid field research that was undertaken. This is perhaps not a gentlemanly issue to raise since it is true of a great many such enterprises in developing countries. Yet, in light of the resources available and the fact that the major obstacle to intelligent analysis of Nigerian agriculture is lack of basic data—number of producers, acres cultivated, input patterns, etc.—I think it is a criticism that needs to be made. As an extreme example, the authors employ a 1963 figure of one million for oil palm producers, citing a "statement by Kilby" (p. 27); the reference was in fact to a casual estimate *en passant* for a quarter of a century earlier (1938)! There are many ways to produce new data—sample surveys, enumerations (the reviewer supervised a complete count of small industry establishments and employment in Eastern Nigeria in three months at a cost of $2,000), analysis of aerial photos, interpolation from other types of data (tax rolls, electoral statistics)—but most of them involve old-fashioned footslogging. While a few of the studies did involve sample surveys of farmers, one almost gets the impression that the four frequently cited doctoral dissertations of Anschel, Thodey, Wells, and Welsch generated more new knowledge than the entire consortium effort. Given the much cheaper cost of doctoral candidates and their greater willingness to suffer the privations entailed in primary data collection, it may well be that such vehicles as the earlier MSU-directed Economic Development Institute, which can mobilize thesis researchers and send them into "the bush," are a more efficient solution than consortia to the problem of developing basic economic knowledge.

PETER KILBY
Wesleyan University

Mueller, Willard F., *A Primer on Monopoly and Competition*, New York, Random House, 1970, xii + 203 pp. ($5.95 cloth, $2.50 paper)

This book by the former director of the Federal Trade Commission's Bureau of Economics surveys at an elementary level the current state of industrial organization knowledge and antitrust policy. It covers an impressive expanse of territory in generally lucid fashion, presumably for an audience of economic principles students and the general paperback-reading public. The presentation is largely descriptive, laced with numbers, case studies, and value judgments. Mathematics and diagrams are absent.

Despite his avowed goal of building a broad-based constituency for vigorous pro-competitive policies, Mueller avoids that shrillness which sometimes afflicts those who have spent eight years in the trustbusting halls on Constitution Avenue. Indeed, Mueller's overall prognosis on the current situation is surprisingly sanguine: he finds that "it is effective competition, not monopoly, that is the rule in American industry." Only when he deals with the F.T.C.'s bête noire, alleged predatory pricing, does he lose his analytic cool, making no effort to draw that fine line between merely vigorous and willfully destructive competition.

Mueller's attempt to present a balanced picture of the U. S. industrial sector's structure and performance and the difficulties of addressing a lay audi

ence interact counterproductively on occasion. After marshalling the evidence that production and research scale economies seldom compel high market concentration, Mueller acknowledges that promotional economies may persist even as consumer goods sellers achieve substantial market shares and absolute size. But he fails to bring out clearly the distinction between real and pecuniary economies, and he builds no solid argument that even real promotional economies might be socially disfunctional. Likewise, he observes that profitability is a leading indicator of industry performance and summarizes the research showing profits to be positively correlated with market concentration. But he only *asserts* that supranormal profits imply resource misallocation, without ever showing how or why. If I were Mueller's typical lay reader who patronizes supermarkets and occasionally buys (or aspires to buy) a share of stock or two, I can see how I might be convinced from his analysis that mergers which reduce unit advertising costs, bolster power to secure discriminatory savings passed on in part to consumers through lower end-product prices, and raise profits are a good thing, to be encouraged—not discouraged—by public policy!

Mueller concludes his work with a set of policy recommendations, including more resources for antitrust enforcement agencies, curbs on major new conglomerate mergers, fuller disclosure of corporate divisional operating results, unspecified solutions to the waxing international trade restriction problem, limitations on interlocking directorates and banks' ntervention in nonfinancial corporation decision making, and a maddeningly vague proposal which may or may not call for more structural divestiture action against existing consolidations of market power.

F. M. SCHERER
University of Michigan

Roy, Ewell Paul, *Collective Bargaining in Agriculture*, Danville, Illinois, The Interstate Printers and Publishers, Inc., 1970, 280 pp. ($6.95)

The title and topic of this book continue to engender considerable interest among persons interested in U. S. agriculture. It is, therefore, logical that such a book describing past, present, and future attempts by agricultural producers and farm workers to improve their economic welfare through collective bargaining should be written. Roy treats four broad topics: the scope of bargaining in U. S. agriculture; economic and legal foundations of these activities; operational aspects of bargaining associations; and alternative means of strengthening the bargaining power of farmers and farm workers.

Unfortunately, the author makes several fundamental errors of fact or judgment that detract from the book's quality. Bargaining power is defined synonymously with *economic* power, whereas the former is actually a subset of the latter (along with market power and political power) [1]. "The ability to influence the outcome of the price-making process" (p. 4) may be a result of several factors, without necessarily encompassing or including the bargaining process. The failure to draw this distinction creates confusion in the reader's mind as to the actual source of power under the various programs and types of legislation discussed.

The statement that "one manifestation of the farmers' lack of bargaining power is their declining share of the consumers' food dollar" (p. 1) is invalid. The farmers' share has not declined significantly during the past 15 years; neither is it a useful measure of bargaining power among participants in the food production-marketing system. A concluding remark that "collective bargaining in agriculture will increase in the years ahead . . ." (p. 225) is also a questionable assertion. Similar other omissions and commissions appear throughout the book. While advancing several ambitious legislative acts needed to stabilize the economic power of U. S. agricultural producers, the author ignores the most important determinant of the success of such programs: political acceptability. Marketing boards are discussed as a legislation-created tool for strengthening farmer bargaining; however, the problems recently encountered by marketing boards in Canada and Europe are not mentioned. These examples suggest that marketing boards (and indeed bargaining organizations) without stringent production control provisions are unable to cope with the basic problem facing U. S. agriculture: excess resources devoted to the production of farm products.

The discussions of farm worker bargaining, interspersed with considerations of bargaining over price and other terms of trade for agricultural products (the primary subject of the text), reduce the book's readability. While farm labor issues are cogent, they could have been treated more effectively in a separate section or in another publication. Nevertheless, the comparisons of farmer bargaining associations with labor unions (Table 4–1, pp. 64–70) are both interesting and useful.

Notwithstanding these limitations, the book does contain a substantial quantity of useful information on cooperative bargaining in agriculture. Chapter 5, "Organizing and Financing Bargaining Associations," is a valuable source of information for anyone contemplating the establishment of such an organization. The first two pages of Chapter 13, "Recommendations for Collective Bargaining in Agriculture," include some excellent observations on the economic limitations of farm bargaining in the absence of effective supply control. The book is better suited "as a handbook or reference for farmers, politicians, educators, journalists and others" (one of its two objectives) than "as a text for students of farm policy and collective bargaining" (Preface).

Scott, A. D., ed., *Economics of Fisheries Management: A Symposium*, Vancouver, The University of British Columbia Institute of Animal Resource Ecology, 1970, vii + 115 pp. ($5.00 paper)

Insofar as published proceedings of a symposium can conform to an orderly, integrated volume, this one is a mild success. There is no question but that significant contributions to fishery economics have been made in this book. An outstanding paper on the theoretical side is that of Quirk and Smith, which will most certainly become a standard reference on the dynamic economics of the fishery. Little can be said with respect to the volume as a whole, so each individual contribution is briefly reviewed.

"Dynamic Economic Models of Fishing" by James P. Quirk and Vernon L. Smith.

As stated by the authors, their principal objective was "to incorporate the externality and growth characteristics of a fishery into a dynamic model of general equilibrium and to compare such a competitive model with a model of optimal fishing over time." Their approach is a rather advanced mathematical one, getting into the representation of solutions of differential equations and application of the Pontryagin Maximum Principle. All of the analysis is done with rigor and imagination.

The presentation begins with a single fish stock, fixed capital endowment, and two consumption goods—fish and other. It is shown that the competitive model is inefficient as a result of the externality associated with the fish stock. The welfare maximization model is used to quantify the necessary tax required to internalize costs in the competitive model and thus overcome the externality. Next, a model with two fish species and an opportunity to change capital stocks is analyzed. After that, the general case of multiple species, capital stocks, and consumption goods is presented. The paper ends with a behavioral model of fishing-investment equilibrium, where investment is a function of the internal rate of return in the industry.

"Some Seasonal Models of the Fishing Industry" by Paul G. Bradley.

The model used by Bradley focuses on intraseasonal management in conjunction with the more commonly analyzed problem of controlling annual harvest. The crux of the problem is an additional decision variable, *viz.*, length of the fishing season, besides the usual one of annual harvest. Also, a differential equation is required to describe population dynamics within the season.

For assumed technology and prices, Bradley arrives at a model with two decision variables: (1) number of boats and (2) length of the season; since only one species is considered, there is one state variable which is population at the beginning of the season. Economic rent from the fishery is maximized with respect to the two decision variables and the equilibrium level of the state variable. A major weakness in the analysis is the tacit assumption of a zero interest rate, at least in determining the opportunity cost of fish stocks. In fact, it can be shown that under a present value criterion, the equilibrium population equation of Bradley's (15-a) will have the interest rate added to its right hand side. This result can be derived from the equilibrium equations given by Burt and Cummings [1].

"The Problem of Achieving Efficient Regulation of a Fishery" by Anthony Scott and Clive Southey.

The central concern here is an institutional arrangement to achieve economic efficiency in a fishery. Three basic organizations are analyzed:

(A) a quasi-market structure where a central agency levies taxes on, buys and sells rights to, participating 'firms';

(B) a completely decentralized multifirm fishery where allocation is entirely through the spontaneous buying and selling of transferable rights—a self-sufficient "market in rights"; and

(C) a single firm within which allocation is achieved through administrative decision or by rule.

"Economic Aspects of International Fishing Conventions" by James A. Crutchfield.

The problems associated with negotiating international controls on fisheries are discussed. A reasonable set of assumptions is specified within which negotiations must take place, and the conclusion is reached that the immediate objective should be the establishment of national quotas, even though this is quite a compromise in economic efficiency. It seems that the only alternatives are achieving minor successes or complete failure. It should also be pointed out that a quota system can be viewed as merely a transition to more favorable methods.

"Price and Allocation over Space" by George G. Judge and Takishi Takayama.

The authors present general models of spatial and temporal allocation, primarily the Takayama-Judge models familiar to most agricultural economists. Little effort is made to adapt the models to the circumstances prevalent in fisheries; and as pointed out by Quirk in his discussion of the paper, externalities are excluded by hypothesis from all industries. But externalities are a central concern in the economics of fisheries management.

"Contractual Arrangements and Resource Allocation in Marine Fisheries" by Steven N. S. Cheung.

The theme here is that contractual arrangements (in the broadest terms) are central to the economics of fisheries. The author even goes so far as to question the concept of externalities as useful and considers his contractual approach superior. There is a definite emphasis on property rights and a government-legal environment conducive to overcoming transactions costs associated with establishment of property rights. The views and arguments presented make one suspicious of the typical panacea for externalities, viz., imposition of a tax by a central agency to internalize the costs. There would seem to be strong arguments for exploring all avenues, with improved means of establishing property rights under relatively small transactions costs as a major course of action.

"Management of Marine Resources: Some Key Problems Requiring Additional Analysis" by Arnold Zellner.

This is a very able survey of some of the directions research should be taking in fishery economics. The major topics are (1) biological relationships; (2) macroeconomic aspects such as demand and supply measurement, dynamic characteristics of movements between equilibria, and stochastic attributes of the problem; (3) microeconomic analysis.

United Nations Economic Commission for Latin America, *Development Problems in Latin America*, Austin and London, University of Texas Press, 1970, 318 pp. ($8.50)

This is a proud book and, for economists, a cautionary one.

In 1949, while the U. S. Government was still advising—nay, lecturing—the less-developed-country governments on the efficacy of free trade and laissez-faire economics for maximizing their national incomes, Raul Prebisch and his group of economists in the ECLA secretariat began to publish a remarkable series of economic studies demonstrating just the opposite. The free-trade economics, they pointed out, suffered from a "false sense of universality." It answered to the circumstances and needs of the industrial countries (the "center") but not to those of the poor countries (the "periphery"). On the contrary, free trade even deprived the latter of some of their contribution to the increase in world product. They needed industrial development—planned—and with trade channeled so as to help.

U. S. officials and trade economists took none too kindly to this back talk. As they saw it, the ECLA case was scientifically wrong but politically powerful because of the cold-war importance of Latin America. Privately, they derided Prebisch's economics (just as they did, incidentally, the economics of agricultural income supports and intergovernmental commodity understandings).

In 20 years, however, they have learned that the U. S. position *also* derives its virtue from political power rather than scientific "objectivity." They have discovered that Prebisch's annoying insistence on a rationale accommodating both of the political elements (the center and the periphery) represents an effort to progress cooperatively toward an economically integrated world. ECLA was creating a new public conceptual environment in Latin America, much as the classical economists once did in England. Frustrating it only encouraged the advocates of autarky and authoritarianism.

This book presents the ECLA case and action proposals, as ECLA has been evolving them in those 20 years and getting some of them adopted. It consists of a concise analytical summary (38 pages), followed by 9 chapters of carefully selected and logically arranged excerpts from official expressions of "ECLA's thinking."

There is first presented a noninvidious explanation of why, over the past century, the Latin American countries have not gotten their share in the increase of world per capita production. With the application of technology in industry, the primary-product countries were supposed (in the laissez-faire theory) to get their share through the reduction of manufactured-product prices (i.e., the improvement of their terms of trade). This did not go very far. Business and labor managed to divert much of the productivity increases to raising their own incomes, which meant prices maintained above economic levels and savings for further industrial investment. A declining portion of the increased incomes was spent for Latin American primary products because of the development of substitutes, protectionism, and the natural tendency of increasing consumption to shift to manufactured products. The periphery had to import the increasing variety of manufactures. Meanwhile, technology in primary production meant unemployment and low wages. Since demand was inelastic, prices fell. Thus industrial products encountered greater demand and primary products lesser. There is built-in disequilibrium for the periphery.

The solution is "inward-directed growth"—industrial diversification of the poor-country economies. Left to the free market, such industrialization as they have is "outward-directed"—not helpful to most of the people. It produces substitutes for the imports least needed. It imposes inflation and devaluation when exports fall. Planning is required to direct industrialization toward infrastructure and the more widely used or essential products, to develop exports of such products in order to reduce

external disequilibrium, to absorb the excess manpower, and to bring along the necessary increase in food production. ECLA has been developing guiding principles for such planning.

A foreign cooperation requirement for this type of industrialization is an adequate and maintained net inflow of capital, to be tapered off as industrialization succeeds. Institutions are needed for assembling and allocating the funds and evaluating the programs. Another requirement is to encourage imports from Latin America, including manufactured products. This results in automatic reciprocity because Latin American imports are limited by their exports.

The all-Latin America requirement is to establish a common market, in spite of vested interests, so that the new industries can enjoy scale economies. Industry must be subsidized less through import restriction and more through export stimulation.

The requirements for the individual Latin American countries are to tax away the excess consumption of the 5 percent of the people who get 30 percent of the personal income and divert it, not directly to the poor, but to increased capital formation (and employment)—including the social capital of education for all and training for workers. Land tenure systems must be changed to encourage social mobility and raise rural living levels. These matters must be put clearly to the people by Latin American economists to achieve public understanding and community action.

This review does not do the argument justice. There is much detail, recognition of problems, and divergent points of view. There are weaknesses, not the least the acceptance of the free-trade economics as valid for industrial countries. But one must appreciate the effective lead given to incorporate a less-developed-country political element into international economics and hope that the intention of the latest of the proposals can be carried out. It will be difficult politically. May economists not contribute technical obstacles!

ROBERT B. SCHWENGER
Kensington, Maryland

Weintraub, D., M. Lissak, and Y. Azmon, *Moshava, Kibbutz, and Moshav: Patterns of Jewish Rural Settlement and Development in Palestine*, Ithaca, Cornell University Press, 1969, xxiii + 360 pp. ($14.50)

Klayman, Maxwell I., *The Moshav in Israel: A Case Study of Institution Building for Agricultural Development*, New York, Praeger Publishers, 1969, xvi + 371 pp. ($18.50)

The historical basis of Israel's social and economic development are the several types of agrarian settlement established in Palestine from the late 19th century. These two books deal with these settlements in very different ways. The Weintraub et al. volume is a sociological interpretation of change and development, analytical and theoretical in approach and conclusions; Klayman is a factual reportage on the economy and administration of one of the three types of settlement (the *moshav*) discussed in Weintraub and is not concerned with social analysis. Weintraub carries the story down to 1948 and the establishment of the new state; Klayman also deals with the past, but is primarily concerned with the present. Weintraub et al. are primarily concerned with an evaluation of the performance of the various types of settlement in the Palestine-Israel context; Klayman is interested in the effectiveness of the moshav as an exportable prototype for agricultural development in other countries. Both books provide information on the role of cooperative mechanisms in agrarian development. The research underlying both books enjoyed American support: Weintraub et al., a team from Hebrew University, Jerusalem, did their work with a grant from the U. S. Department of Agriculture; Klayman did part of his work (a chapter on Venezuelan adaptations of the moshav) while employed by the Inter-American Development Bank, the balance on the basis of financial support from the University of Pittsburgh.

Weintraub et al. are concerned with a sociological history of the various types of settlements of Jews in Palestine under Turkish and British rule, roughly down to the establishment of the Israeli state: the *moshava*, or colony; the *kibbutz*, or collective; and the *moshav*, or cooperative settlement. This history is presented in terms of five major themes: the nature of the original colonizing traditions that produced the three types; the social environment in which the different settlements were established; the growth potential of the different types and their actual achievements; the internal capacity of the types of settlement to develop and adapt to changing conditions; the kind of participation in the majority institutions of the developing overall Jewish settlement of Palestine. The information is presented in three blocks of chapters: the first is concerned with three case studies of the settlement types; the second with the history of development of the three types; the third with a general comparative analysis of the three in line with the five themes.

Part 1, with its case studies, was for this reviewer the most interesting, since it presents detailed analyses of how the institutions of the three settlements responded to the changing conditions of Palestine. Essentially this is a story of social adaptation; that is, change presented as the record of conscious adjustments under the constraints and flexibilities imposed by the traditions and other circumstances of the original settlement. Petach Tivka, the first successful colony, now a thriving large town near Tel Aviv, is used as the type example of the moshava. Founded by orthodox European families, determined to make an independent agricultural

settlement, the colony had its ups and downs, as various agencies controlled the waves of settlement and because of internal conflicts among the heterogeneous settlers. The original ideal stressed the transformation of the ghetto Jew into a sturdy, smallholding farmer and villager, with mutual aid mechanisms tying together the farm families, but without change in basic Jewish traditions and social organization. As the village found suitable crops (orchards, mainly), economic institutions took over and the original vague idealism was lost in a drift toward a prosperous agricultural community with internal differentiation. Outside labor was hired, and the colony solidarity disappeared. As population increased and economic success blossomed, conflicts diminished, but so did the original community; and Petach Tivka wound up as an ordinary differentiated commercial town, the center of a citrus industry.

Ein Harod is selected as the prototype of the kibbutz, and if not the very first, it was very early and experienced all the stages and phases of kibbutz development. The original collective settlements in Palestine were called *kvutza* (group) and were small communities raising single crops, living by egalitarian, communal, *gemeinschaft* principles, designed to provide a complete new Jewish social organization. Around World War I this idealistic formula had proved nonadaptive to the constraints of the natural and economic environment: the inadequate land base and agricultural specialization had led to increasing debt, and the small size of the groups contributed to severe internal tension. The solution was the emergence of the larger, more diversified and rationalized kibbutz. The authors make clear that the kibbutz form emerged mainly out of necessity, as an adaptive solution to the need for increased diversification, labor, and capital, but with considerable stimulation from Russian Jewish immigrants bearing Utopian and Marxist ideas. The kibbutz template preserved the basic ideals of the kvutza—the complete transformation of the European ghetto Jew—and accepted a dynamic, experimental format: the model of economic growth in a collective community with a growing population. What remained of consumption austerity was considered to be for practical reasons only; "voluntary asceticism" was renounced. This dynamic environment had its social costs in the form of factionalism and cleavage, the detached groups leaving to form new kibbutzim. Growing specialization led to "secondary institutionalization" to control the divisive effects of status and prestige differences and to preserve the basic forms of an egalitarian democracy, which have proved to be successful compromises. The flexibility of the kibbutz pattern is thus created by the fact that it provides for a considerable number of choices on the part of its members, even while maintaining considerable collective control over social life, the rearing of children, and decision making. Given the small size of the political entity, Palestine-Israel, and the growing integration of the entire economy, no collective settlement could hope to remain as isolated and aloof as the Hutterites in their remote and underpopulated northern Great Plains.

Nahalal, like Petach Tivka the first of its breed, is presented as the type case of the moshav, or smallholders' cooperative farm settlement. Its founders, mostly out-of-work agricultural laborers from colonies, aimed at something midway between the individualistic colony-town and the kvutza-kibbutz collective. Essentially, this meant that the distinction between the private and community spheres of autonomy and control, defined and chartered in the collectives, was left open for evolutionary emergence in the moshav. Cooperative economic institutions were built into the system to spread risks and lighten the burden of capital acquirement; but beyond this the farmer-members of the moshav were free to determine their own lives, consumption, and social participation. The moshav thus creates a "strain" in its fabric: the supraorganization of the cooperative, with its dedication to economic rationality and integration into the national economy, is a "modern" element; but the small farmer and his modest, individual life is a "peasant" element.

In any case, integration was to be assured by cooperative labor, marketing, credit, machinery, devices, and by a circular community plan, with the houses surrounding public buildings and the radial, wedge-shaped fields around the houses. Integration was confronted, however, with the same economic forces that were influencing the colony and the kibbutz: the needs for greater efficiency, diversification, and rationality, which required hired labor and threatened the egalitarian smallholder farm pattern. "Rampant development" by the ambitious was curbed by land redivision to give the second generation their own farms, a solution that created too many substandard units. Hence there has been a drift out of agriculture into urban jobs on the part of the less successful farmers and a continued tendency for the better farmers to make more money. Still, the authors say this has been kept in control and Nahalal remains a relatively conservative and egalitarian community.

In the final chapter on comparative analysis, the authors summarize the different adaptations made by the three types of settlement to the changing conditions of Palestine. With respect to economic matters, Petach Tivka, with the least specialized ideology, changed toward commercial agriculture most rapidly and extensively. The kibbutz, with the most clearly formulated utopian social charter, had to accept change formally and with conflict and doubt, not unconsciously as Petach Tivka. While the changes went in the same direction, they were more in the nature of compromises with the communal system. Nahalal stands somewhere between the other two settlements. The authors find that

while Petach Tivka has an economic secularism which promotes rapid growth, the ideologically-guided policies of the other two settlements result in more intelligent control of development. However, as between the moshav and the kibbutz, the latter has proven to be more flexible, since its communal controls avoid the contradictions of independent smallholding with rational integration. Still, the kibbutz is "socially expensive," is prone to certain economic weaknesses, and is moving toward light industry; the moshav can more easily sustain its agrarian base, conflicts notwithstanding. No clear preference can be expressed between these three groups from the standpoint of economic success, and the authors go along with the Hirschman multilinear path theory of development. However, although the authors do not mention it, one possible single standard might be ecological: the sustained-yield system of using resources. The reviewer's own observations in Israel would suggest that in this respect the kibbutz would probably come out ahead.

This is the best single work to date on the settlements of Israel, since it makes a comparative analysis of various dimensions of adaptive change. However, with some exceptions the story ends in 1948, and the reader cannot help wishing the writers had brought their study down to the present. Most of the adaptations visible in 1948 have continued, with predictable associated tensions. Perhaps a second volume is in view.

Klayman's book is really a wide-ranging treatise on certain aspects of agrarian development, using the moshav (*olim* and *ovdim* types) as a center of gravity. He provides a history of agrarian settlement in Palestine-Israel that parallels Weintraub et al., although pointed more toward economic considerations. There are chapters on the organization and planning of Israeli agriculture as a national entity; several chapters on the moshav, with special attention to economics; and several chapters on agricultural development problems and the advantages and disadvantages of the moshav form as a "package" for certain types of countries. Klayman seems to come down harder on the advantage side since he recognizes that the moshav combines a number of desirable features: it contains both the municipal and the agrarian institutions needed for the rapid development of village agriculture; it contains necessary risk-spreading cooperative mechanisms but without the commitment to a special social charter as in the case of the kibbutz; that is, it avoids extreme collectivism, which so often fails in countries with traditional kinship-dominated and particularistic social systems, since it preserves the smallholder-family production unit. It is in effect a compromise between the large commercial farm and the small family-type farm.

Klayman provides two chapters on two countries where moshav-type experiments have been instituted: Venezuela and Iran. In Venezuela the program was set up with the assistance of an Israeli team, which established a training program as well as settlement assistance. The Venezuelan land reform was the occasion for the experiment, and Klayman concludes that the moshav has been a success in providing a workable frame for new smallholder agriculture, increasing its productivity and at the same time conserving social and economic traditions. The Iran case is quite different: only one large experimental project is involved, and the peasants are manipulated from above; they are not part of an agrarian reform movement which campaigned for land reform, as in Venezuela. Klayman finds it not possible to make a conclusive evaluation and cites numerous difficulties, paramount among them being the failure of the peasants to identify with the project.

At one point in his book Klayman uses Nahalal as one "micro example" of a moshav, and the information contained in this section nicely supplements the description in Weintraub et al. In keeping with his overall emphasis, Klayman provides detailed economic data that illustrates the tendency toward differentiation in efficiency, income, and specialization among the moshav families and the tendency to acquire nonfarm employment among the less productive units. He also states that Nahalal "is not a typical moshav, as it is better than average," which might raise a question about the Weintraub et al. choice of cases. However, while Klayman is interested in economic performance, Weintraub et al. are concerned with settlement styles, and hence economic typicality is not a necessary consideration.

There is an apparent contradiction in the Klayman and Weintraub approaches in that Klayman sees the moshav as an effective institution, transferrable to other countries, while Weintraub et al. see no strong advantage for the moshav over the kibbutz and the colony. However, Klayman is dealing with transnational economic institutions and Weintraub et al. with the special environment of Israel. From these two books alone it is not possible to obtain a clear picture of the cross-cultural significance of these various Israeli types of agrarian organization.

Klayman is of course convinced of the desirability of organized cooperation in facilitating agrarian development in the emerging countries. While his approach is objective, he nevertheless does not consider alternatives to organized cooperative institutions at the production level, informal diffuse systems of exchange which might accomplish the same ends. As in Weintraub et al., there is no consideration of ecological matters; from neither book do we acquire a feeling for the relative merits of different production schemes for conservation and use of resources. Both books thus belong to the older generation of agrarian development literature, the generation which does not question development per se and does not see it in the larger context of the human use of the earth.

JOHN W. BENNETT
Washington University at St. Louis

Williams, Sheldon W., David A. Vose, Charles E. French, Hugh L. Cook, and Alden C. Manchester, *Organization and Competition in the Midwest Dairy Industries*, Ames, Iowa State University Press, 1970. 339 pp. ($12.50)

Regional research projects do not ordinarily contribute much to wisdom and understanding in agricultural economics, but this study of the dairy industry is a notable exception. It is the best regional research study this reviewer has ever come upon, indeed one of the best industry studies from any source.

The authors have summarized and drawn off the essence of nearly all the significant economic research done in recent years relating to the dairy industry, but they have done much more than this. They have demonstrated how to make a comprehensive, pragmatic, and perceptive analysis of a complicated industry—something one doesn't come across often in agricultural economics these days. This book should be of interest to dairy farm leaders and business men as well as agricultural economists, and it should be of special value to graduate students and young economists as an example of activist research on significant economic matters. It deserves an influence in agricultural economics far beyond the dairy industry.

Chapters 1 and 2 provide a quick summary of what has been happening in the dairy industry, and why. Topics include dairy farming, demand and consumption, industry developments (large companies, retailing, wholesaling), price and cost behavior, federal orders, price support programs, technological developments, plant operations, business organization, and numerous others. For anyone having only limited time to spend with this book, these first two chapters (pp. 3–56) and the last two (pp. 260–308) are the best to read.

Chapters 3 to 9 (pp. 57–224) provide detailed discussion and analysis of each segment of the dairy industry. Here the relevant statistics and results of other studies are brought together and supplemented with some new research and the informed opinion of the numerous contributors to the regional project itself. The analysis is in terms of market structure and its relevance for conduct and performance. This major part of the book is an excellent compendium of economic information about nearly all phases of the dairy industry and provides a good reference source.

Chapter 10 is an analysis and appraisal of industry performance in terms of such factors as technological efficiency, optimum plant and firm size, progressiveness, labor productivity, margins and profits, sales promotion costs, etc. In judging industry performance, the authors postulate "workable" rather than "perfect" competition as a socially acceptable goal; they accept not only the inevitability but also the desirability of modern industrial structure, and they understand its workings. They give the industry about average marks on performance, or maybe in some respects a little better.

One of the shortcomings of the book is its failure to provide adequate treatment of the economics of enterprise scale and its implications for ultimate market structure. There is the usual analysis showing how plant costs decline with increasing volume within the ranges of observation, and a labored effort is made to discover the minimum optimum size of dairy plants by Stigler's "survivor analysis" (based on his self-evident proposition that "the competition of different sizes of firms or plants sifts out the more efficient enterprises"). But nowhere does there seem to be recognition that as a practical matter plant size is limited mainly by the requirements of the market for its products and by transportation factors, rather than by any diseconomies of scale in the operation of the plant itself.

More serious is the failure to treat more fully the economics of scale in terms of promotion and distribution, vertical and product integration, financing, business management, etc. The authors are clearly aware of these elements as primary determinants of market structure, and they point out that the tendency to large scale is probably the dominant characteristic of the dairy industry in recent decades. But somehow they never bring themselves to a direct confrontation with the matter of enterprise scale and what to do about it, which is certainly one of the key economic issues of our time. This is the more regrettable, since some of the contributors to this study have an extraordinary degree of economic sophistication, and one wishes they had thrown caution and academic inhibitions to the winds and swung into it.

The final chapter 12 shows the authors at their best. It is what they term "a relevant compilation of ideas," and it is incisive and provocative and treats of many things and issues. It is must reading for anyone interested in any phase of the dairy industry.

One wishes that the fine team which produced this general study of the dairy industry would not now be disbanded but could take up specifically and in depth some of the important new problems confronting the industry, such as:

Will dairy farming move toward large-scale factory-type units such as those in the poultry and beef industries, or has dairying special characteristics that will prevent this?

What is the future of the demand for dairy products in view of their less favorable health image, nondairy substitutes, and changes in the eating habits of people?

What structural changes are in prospect for the dairy industry with respect to mergers, large vs. small distributors, the retail chains, the coops, and the newly-formed big producer bargaining groups? And what, if anything, should be done about them?

A. C. HOFFMAN

Webster, John, *Introduction to Fungi,* Cambridge, Cambridge University Press, 1970, viii + 424 pp. $10.50.

Announcements

ANNUAL MEETING
AMERICAN AGRICULTURAL ECONOMICS ASSOCIATION
Southern Illinois University
Carbondale, Illinois
August 15-18, 1971

Format of the 1971 Annual Program

Some variations in programming were tried by Dale Hathaway last year, and I shall follow essentially the same format. The self-initiated scholarship that regularly is submitted to *AJAE* will form the bases for discussions at the Annual Meeting. The Editor has kept me informed of the flow of manuscripts that have been reviewed and accepted for publication in the Journal. Insofar as these papers have offered subject matter that can be integrated into general topics chosen for the Annual Meeting program, I have invited the authors to summarize and discuss the results of their research. This applies to papers that have already been published in issues of the Journal preceding the Annual Meeting and to those accepted for publication in later issues. Above all, I take the position that the program should be for those who attend.

There is no thematic design for the annual meeting; hence I shall expect to invite a heterogeneous variety of papers. However, these papers will not be automatically published as in the past. Authors of papers may, at their option, present manuscripts based on their papers for review and possible publication in the Journal in the same manner as others seeking publication in the February, May, August, and November issues.

The Proceedings issue (December) will contain abstracts of all papers presented and discussed at the Annual Meeting, regardless of whether an article has already been published or accepted for publication. As heretofore, the December issue will also contain the Presidential Address, the invited general seminar papers, committee reports, and Association business.

For the Proceedings issue, abstracts can be longer (maximum 250 words) than for regular articles (these are having to be restricted to 100 words to qualify for the *Journal of Economic Literature*). Additionally, if a practical method can be devised, the Proceedings issue will carry summaries of the remarks by those participating in the discussions. We are still experimenting with this method.

The major deviation from last year's format relates to contributed papers. In the general seminar subject matter areas, contributed papers will be accepted. C. E. French, Purdue University, assisted by the program organizers for the general seminar sessions, will decide on contributed papers policy. Topical areas for the seminars follow.

General Topical Areas for Seminars at Annual Meeting

1. International Agricultural Adjustment
   Program Organizer: Lyle P. Schertz
   Deputy Administrator
   Foreign Economic Development Service
   U. S. Department of Agriculture
   Washington, D.C. 20250

2. Rural Development, Community Development, and Human Resources
   Program Organizer: Henry J. Meenan, Head
   Department of Agricultural Economics
   University of Arkansas
   Fayetteville, Arkansas 72701

3. Organizing and Financing Agricultural Production in the 70's (Macro Problems)
   Program Organizer: Eric Thor, Administrator
   Farmer Cooperative Service
   U. S. Department of Agriculture
   Washington, D.C. 20250
4. The Role of Forestry and Natural Resources in Economic Development
   Program Organizer: Hans M. Gregersen
   School of Forestry
   110 Green Hall
   University of Minnesota
   St. Paul, Minnesota 55101
5. The Impacts of Changing Technology and Institutional Forces on the Management of Agricultural Firms (Micro Problems)
   Program Organizer: W. Neill Schaller
   Associate Director
   Farm Foundation
   600 S. Michigan Avenue
   Chicago, Illinois 60605
6. Environmental Quality Problems; Nature, Causes, and Approaches to Solutions: Implications for Agricultural Economists.
   Program Organizer: Kenneth R. Tefertiller, Head
   Department of Agricultural Economics
   University of Florida
   Gainesville, Florida 32601

In addition to these major seminar areas, of course, there will be the principal addresses of the morning sessions; the sectional papers on specific topics, selected from suggestions of the membership; the other parts of the program, such as the Fellows Address, Awards, etc.

JIMMYE S. HILLMAN, *President*

AAEA COMMITTEE STRUCTURE, 1970-1971

Awards Committee

Chester Baker, Chairman, Illinois, 1967

Distinguished Undergraduate Teacher Award

John Malone, Jr., Chairman, Nevada, 1968
John Timmons, Iowa State, 1968
Milton Snodgrass, California Polytechnic, 1969
Jack Thompson, Georgia, 1970
David K. Armstrong, Michigan State, 1970
Bob Christensen, Massachusetts, 1970
John Neal, Texas A&M (student)

Extension Award

Gene McMurtry, Chairman, Virginia Polytechnic, 1969
Charles Beer, FES, USDA, 1969
John Bottum, FES, USDA, 1970
Clarence Klinger, Missouri 1968
Henry Meenan, Arkansas, 1970
Ray Penn, Wisconsin, 1969
Luther T. Wallace, California, Berkeley, 1970
Jean Wyckoff, Massachusetts, 1970

Published Research Award

J. O. Gerald, Chairman, ERS, USDA, 1969
Dale Knight, Kansas State, 1969
Bud Stanton, Cornell, 1969
Howard Williams, Ohio State, 1969
M. L. Lerohl, Ottawa, Ontario, 1969
Joseph Havlicek, Jr., Purdue, 1969
Bill Martin, Arizona, 1970
William Motes, EDD, ERS, USDA, 1970
Billy Lessley, Maryland, 1970
Walter Butcher, Washington State, 1970
Carlton Dennis, Agway Corporation, 1970
J. A. Seagraves, North Carolina State, 1970
Lee Bawden, Wisconsin, 1970

Master's Thesis Award

Eldon Weeks, Chairman, Washington State, 1967
Dale Anderson, North Dakota State, 1969
Wallace Rehberg, Washington State, 1970
Tom Hady, ERS, USDA, 1969
Leroy Quance, Oklahoma State, 1969
Jim Kendrich, Nebraska, 1969
Robert Rizek, ERS, USDA, 1969
David Allee, Cornell, 1970
Bob Herdt, Illinois, 1970
Tom Williams, Southern U., Louisiana, 1970
Jim Youde, Oregon State, 1970
Eric Oesterle, Purdue, 1970
Steven Lytle, Clemson, 1970

Ph.D. Dissertation Award

Willard Williams, Chairman, Texas Tech., 1967
Burl Back, USDA, 1969
Gail L. Cramer, Montana State, 1969
Joe Purcell, Georgia, 1969
Wayne Purcell, Oklahoma, 1969
Walt Miller, ERS, USDA, 1970
Fred Tyner, Florida, 1970
Verner G. Hurt, Mississippi State, 1970
Frank Orazem, Kansas State, 1970
Don Farris, Texas A&M, 1970
Frank Smith, Minnesota, 1970
Hugh Cook, Wisconsin, 1970
Dan Bromley, Wisconsin, 1970
Royce Hinton, Illinois, 1970

Audit Committee

Fred E. Justus, Kentucky, 1970
Jim Criswell, Kentucky, 1970

Bibliographical Committee

Lee Day, Chairman, Pennsylvania State, 1969
Fred Abel, USDA, 1969
Ivan Schmedemann, Texas A&M, 1970
Edwin Farris, Virginia Polytechnic, 1970
W. Darčovich, Canada Dept. of Agriculture, 1970

Brochure Committee

Ralph J. Mutti, Chairman, Illinois, 1969
Sydney James, Iowa State, 1969
Dave Downey, Purdue, 1969

Directory Committee

Bob Rudd, Chairman, Kentucky, 1969
John Redman, Kentucky, 1969
Clifton Cox, Armour, Chicago, 1969
Burt Sundquist, USDA, 1969

Educational Committee

James Nielson, Chairman, Washington State, 1969
Lester Manderscheid, Michigan State, 1969
Linley Juers, ERS, USDA, 1969
Fred Mangum, North Carolina State, 1969
Oscar Hoffman, Northbrook, Illinois, 1969
John Helmberger, Minnesota, 1969
John Wildermuth, Arizona, 1970
Lee Kolmer, Iowa State, 1970
John McNeely, Texas A&M, 1970

Economic Statistics Commiteee

James Bonnen, Chairman, Michigan State, 1969
John Schnittker, Kansas State, 1969
George Tolley, Chicago, 1969
James Hildreth, Farm Foundation, 1969
George Judge, Illinois, 1969
Harry Trelogan, USDA, 1970

Employment Services Committee

Loys Mather, Chairman, Kentucky, 1968
David H. Boyne, Ohio State, 1969
Almon T. Mace, Madison College, 1969
Melvin Janssen, ERS, USDA, 1969

Extension Affairs Committee

Eber Eldridge, Chairman, Iowa State, 1968
Wallace Barr, Ohio State, 1969
John S. Bottum, ERS, USDA, 1970
Neill Schaller, Farm Foundation, 1970
Henry Wadsworth, Purdue, 1970
Clay Moore, Texas A&M, 1970

Fellows Election Committee

George Brandow, Chairman, Pennsylvania State, 1966
Harry Trelogan, USDA, 1967
Maurice Kelso, Arizona, 1968
Nathan Koffsky, Washington, D.C., 1969
Glenn Johnson, Michigan State, 1970

Industry Committee

Charles Erickson, Chairman, Cargill & Co., 1968
William Bunkers, Anheuser-Busch, 1968
George Allen, W. R. Grace & Co., 1969
Vern Schneider, Am. Inst. of Cooperation, 1970
Dick Goodman, Cook & Co., 1970
Claude Scroggs, Southern States Coop., 1970
Paul Baumgart, Safeway Stores, 1970
Jerry Quackenbush, ADA, 1970
Glenn Heitz, Federal Land Bank, 1970
Ray Seltzer, Dunlap & Associates, 1970
Shelby Robert, Pet, Inc., 1970

International Committee

Erik Thorbecke, Chairman, Iowa State, 1969
Walter Falcon, Harvard, 1966
Wyn Owen, Colorado, 1968
Eldon Smith, Kentucky, 1969
Nicolaas Luykx, East-West Food Institute, 1970
Earl Heady, Iowa State, 1970
Tony Tang, Vanderbilt, 1970
Max Myers, South Dakota State, 1970
Lyle Schertz, FES, USDA, 1970

Investment Committee

John Redman, Kentucky, 1969
Del Kearl, Cornell, 1958
Dale Butz, Illinois Agricultural Assn., Bloomington, 1970

Membership Committee

Quentin West, Chairman, 1965
E. E. Broadbent, 1969
LaVon S. Fife, 1968
Del Kearl, 1958
N. Keith Roberts, 1968
Fred H. Wiegmann, 1968
T. T. Williams, 1968

Sustaining Membership Subcommittee

Del Kearl, Chairman, Cornell, 1964
S. Kent Christensen, National Assn. of Food Chains, 1965
Charles Sayre, Staple Cotton Coop. Assn., 1965
Lauren Soth, Des Moines Register and Tribune, 1965
Roy Stout, Coca Cola, Atlanta, 1970
Joe Marshall, Cotton Producers Assn., 1970
Ray Seltzer, Dunlap and Associates, 1970

Nominating Committee

Dale Hathaway, Chairman, Michigan State, 1970
Chester Baker, Illinois, 1970
John Bottum, ERS, USDA, 1970
William Folz, Idaho, 1970
Marshall Godwin, Texas A&M, 1970
Richard Goodman, Cook Industries, Inc., 1970
Linley Juers, ERS, USDA, 1970
John Redman (ex-officio), Kentucky, 1970

Postwar Literature Review Committee

Lee Martin, Chairman, Minnesota, 1967
Glenn Johnson, Michigan State, 1967
Maurice Kelso, Arizona, 1967
John Doll, Missouri, 1968
Louis Upchurch, USDA, 1967
Pat Madden, Pennsylvania State, 1969
Peter Helmberger, Wisconsin, 1969
Ed Tyrchniewicz, Manitoba, Winnipeg, 1969

Professional Activities Committee

James Hildreth, Chairman, Farm Foundation, 1968
Eber Eldridge, Iowa State, 1969
Kenneth Tefertiller, Florida, 1968
Louis Upchurch, USDA, 1968
Jim Nielson, Washington State, 1970
Erik Thorbecke, Iowa State, 1970
Charles Erickson, Cargill & Company, 1970
Ray Farrish, Connecticut, 1970
James Plaxico, Oklahoma State, 1970

Student Affairs Committee

John Sjo, Chairman, Kansas State, 1969
Robert Beck, Kentucky, 1968
Donald G. Smith, Illinois, 1968
Lowell Wilson, Auburn, 1968
Bob Koch, Rutgers, 1969
Leo V. Mayer, Iowa State, 1970
Don J. Epp, Pennsylvania State, 1970
Dan Badger, Oklahoma State, 1970

Tellers Committee

Frank Bordeaux, Jr., Kentucky, 1970
Bruce Beattie, Kentucky, 1970

Visiting Professor Committee

James Hildreth, Chairman, Farm Foundation, 1969
Emiel Owens, Minnesota, 1969
John Thompson, South Dakota State, 1969
Andrew Vanvig, Wyoming, 1969

AAEA Representative to National Research Council

George Brandow, Pennsylvania State, 1970

AAEA Representative to National Bureau of Economic Research

Harold Halcrow, Illinois, 1970

AAEA Liaison to American Society of Agronomy

C. R. Hoglund, Michigan State, 1970

Local Arrangements, Winter, 1970

Ed Jones, The Michigan Bank, Detroit

Local Arrangements, Summer, 1971

Walter J. Wills, Southern Illinois University

WESTERN AGRICULTURAL ECONOMICS ASSOCIATION

The 1971 Annual Meeting of the Western Agricultural Economics Association will be held at Squaw Valley, California, July 25–27.

News Notes

CORNELL UNIVERSITY

APPOINTMENTS: **Richard Boisvert,** formerly of the University of Minnesota, and **L. Duane Chapman,** formerly of the University of Tennessee, assistant professors.

ECONOMIC RESEARCH SERVICE, USDA

(EDD is Economic Development Division; ESAD is Economic and Statistical Analysis Division; FDTD is Foreign Development and Trade Division; FPED is Farm Production and Economics Division; FRAD is Foreign Regional Analysis Division; MED is Marketing Economics Division; NRED is Natural Resource Economics Division.)

APPOINTMENTS: **Warren R. Bailey,** formerly deputy director, FPED, acting director; **Everet Wayne Denny,** FRAD; **Samuel L. Donald,** USDA liaison officer, Alcorn A&M College, Lorman, Mississippi; **Gerald Feaster,** MED: **Ralph G. Forsht,** NRED, University Park, Pennsylvania; **Richard L. Harwell,** FPED, Stillwater, Oklahoma; **Richard M. Kennedy,** USDA liaison officer at Virginia State College, Petersburg, Virginia; **Charles A. O'Dell,** USDA liaison officer at Prairie View A&M College, Prairie View, Texas; **William H. Pietsch,** NRED, Pullman, Washington; **Bobby Robinson,** FPED; **Herbert W. Steiner,** FRAD; **W. B. Sundquist,** formerly director, FPED, acting deputy administrator, ERS.

LEAVE: **Alan R. Bird,** EDD, to the National Area Development Institute.

TRANSFERS AND REASSIGNMENTS: **Sanford Belden,** MED, from Lafayette, Indiana, to Cornell University; **Max Bowser,** MED, from University Park, Pennsylvania, to the Agricultural Stabilization and Conservation Service, Washington, D.C.; **Cleveland Eley,** from Office of Administrator to MED; **William P. Huth,** from FDTD to Foreign Agricultural Service; **Joe Imel,** MED, from Madison, Wisconsin, to Washington, D.C.; **John Lawler,** from MED to ESAD, Washington, D.C.; **Theodore Moriak,** MED, from Albany, California, to Washington, D.C.; **Richard C. McArdle,** from NRED to FRAD; **C. Kyle Randall,** from Office of the Secretary to outlook and situation officer, Office of Administrator; **Gary Taylor,** from NRED to National Water Commission, Washington, D.C.; **Glenn R. Samson,** from FRAD to PASA assignment in Lesotho and Swaziland; **Duane Smith,** MED, from University of New Hampshire to University of Maine.

FOOD RESEARCH INSTITUTE, STANFORD UNIVERSITY

APPOINTMENTS: **Arjun Adlakha,** Ph.D. Michigan, research demographer; **Sven W. Arndt,** California at Santa Cruz, visiting professor, Spring Quarter 1971; **Tetteh A. Kofi,** Ph.D. California, acting assistant professor, 1970–1971; **Kenneth A. Leslie,** University of the West Indies, Kingston, Jamaica, visiting scholar, 1970–1971.

LEAVES: **Scott R. Pearson,** assistant professor, economist, Presidential Commission on International Trade and Investment Policy, 1970–1971; **Peter Timmer,** assistant professor, associate advisor to the Indonesian Government with the Development Advisory Service of Harvard University, 1970–1971.

UNIVERSITY OF ILLINOIS

APPOINTMENTS: **H. J. Schweitzer,** formerly associate professor, assistant director of Cooperative Extension Service and assistant director of the Experiment Station.

LEAVES: **Harold G. Halcrow,** sabbatical, six months, Stanford Food Research Institute and University of California, Berkeley; **J. C. van Es,** visiting assistant professor Department of Rural Sociology, University of Wisconsin, seven months ending August 31, 1971.

ARTHUR D. LITTLE, INC.

APPOINTMENTS: **Richard J. Lacroix,** University of Campinas, Brazil, special consultant in agribusiness; **John M. Lovorn,** FHA, USDA, staff consultant in agribusiness; **Dennis H. Wood,** J. D. Harvard, staff consultant in agribusiness.

TRANSFERS: **Robert E. Lee,** from Arthur D. Little, Inc., Cambridge, to Arthur D. Little, Ltda., Belo Horizonte, Brazil; **Harry Trask,** from Fertilizer and Chemical Group to Agribusiness Group.

UNIVERSITY OF MISSOURI

APPOINTMENTS: **Francis P. McCamley,** formerly of Oklahoma State University, assistant professor; **Johannes deGraaf,** M.S. Massachusetts, instructor.

AWARDS: **Randall E. Torgerson,** Curators Publication Award for 1970, for *Producer Power at the Bargaining Table* (University of Missouri Press)—first recipient of this award for best book published by an assistant professor; **Donald R. Levi,** Gamma Sigma Delta Junior Faculty Award of Merit.

MONTANA STATE UNIVERSITY

APPOINTMENTS: **Donald K. Rose,** Ph.D. Colorado, and **Gilbert G. Biebink,** J.D. Minnesota, staff.

OHIO STATE UNIVERSITY

APPOINTMENTS: **Reed Taylor,** formerly with Monsanto, associate professor; **David Francis,** Ph.D. Cornell, assistant professor.

LEAVES: **Howard Steele,** sabbatical, Foreign Economic Development Service, Washington, D.C., until January 1972; **Howard Williams,** sabbatical, American Stabilization and Conservation Service, Washington, D.C., until February 1972.

UNIVERSITY OF WISCONSIN

APPOINTMENT: **Gayle S. Willett,** Ph.D. Wisconsin, assistant professor.

LEAVE: **William E. Saupe,** to participate in University of Wisconsin-AID program for agricultural development at Federal University of Rio Grande do Sul, Brazil, two years.

OTHER APPOINTMENTS

Peter J. Barry, formerly of the University of Guelph, assistant professor, Texas A&M University.

Meir Chayat, Ph.D. Cornell, Planning and Development Center, Ministry of Agriculture, Tel Aviv, Israel.

James M. Conrad, Ph.D. Kentucky, head of Department of Business Administration, Northwood College, West Baden, Indiana.

Harold Cosper, Ph.D. Nebraska, Natural Resource Economics Division, ERS, USDA, stationed at Oxford, Mississippi.

Robert D. Dahle, extension associate professor of economics, North Carolina State University.

Gerald Feaster, Ph.D. Kentucky, Market Development and Performance Branch, MED, ERS, USDA.

Carroll Garner, M.S. Arkansas, instructor, University of Arkansas.

Brook A. Greene, Ph.D. Cornell, assistant professor, American University, Beirut.

Thomas I. Gunn, chairman of newly established Department of Agricultural Economics, Fresno State College, Fresno, California.

Bernard Hoffnar, formerly with ERS, USDA, consultant to Office of Planning, Research, and Evaluation, Office of Economic Opportunity, Washington, D.C.

John D. Hyslop, Ph.D. Minnesota, agricultural economist, Foreign Economic Development Service, USDA.

Larry C. Jenkins, Ph.D. Kentucky, University of Missouri-Rolla.

Gary Keathley, formerly of the University of Arkansas, assistant director of commodity department of Arkansas Farm Bureau Federation.

Eugene Anderson Laurent, Ph.D. Clemson, assistant professor, Environmental Resources Center, Georgia Institute of Technology.

Barry R. Lawson, graduate student Cornell, assistant professor, Wayne State University.

Larry Seistritz, Ph.D. Nebraska, agricultural economics staff, North Dakota State University.

Jack N. Lewis, formerly of the University of New England, Australia, director of corporate planning for the international Wool Secretariat, succeeding **E. G. Carter** on his retirement in July.

Chuan Chian Lim, Ph.D. Missouri, University of Missouri Extension Division.

Gaines Howard Liner, Ph.D. candidate, Clemson, assistant professor of economics, University of North Carolina.

Ronald G. Lorentson, Ph.D. candidate, Washington, acting assistant professor, University of California, Berkeley.

Ralph Gene Martin, formerly of the University of Arkansas, director of soybean division of Arkansas Farm Bureau Federation.

Wayne Pfeiffer, Ph.D. Nebraska, Provincial Department of Food and Agriculture, Toronto, Canada.

Charles Robertson, Ph.D. Cornell, Overseas Development Administration, London.

Wayne A. Schutjer, Pennsylvania State University, director of the Research and Training Network of the Agricultural Development Council, New York.

Geoffrey Shepherd, ret. Iowa State University, chief economist of Indonesia Rice Marketing Team, Djakarta, for Weitz-Hettelsater Engineers under contract to USAID, six months.

Arlen Skarr, Ph.D. Nebraska, economics staff, Mankato State College, Mankato, Minnesota.

Martin Lonnie Spurgeon, Ph.D. Missouri, Mid-America Dairyman, Springfield, Missouri.

Arthur I. Strong, III, Ph.D. Wisconsin, program planner with Bureau of Budget, City of New York.

Eric Tollens, Michigan State, faculty of University of Louvain, to be stationed at Kinshasa, Congo, Africa.

Joseph S. Weiss, Ph.D. Cornell, Louis Berger, Inc., Consultants, Tehran, Iran.

OTHER LEAVES

Garland Wood, Michigan State University, returned from Balcarce, Argentina, where he was chief of party, MSU/AID.

OBITUARIES

Elwyn Loomis Cady, Sr., 72, agricultural economist and lawyer, died in December 1970 at Independence, Missouri. Born in Meadville, Missouri, he received his bachelor's degree at the University of Missouri, master's and doctorate degrees at Iowa State University, and a doctor of laws degree at the University of Missouri-Kansas City.

Cady served as an agricultural extension marketing specialist at Iowa State University from 1921 to 1938. During that time he also spent three summers with the U. S. Department of Agriculture where he aided in drafting the federal crop insurance act. After periods of service with the Office of Price Administration in World War II, he held several positions in private industry in Turkey and Newfoundland and in Kansas City.

In the past ten years Dr. Cady had practiced law with his son, Elwyn L. Cady, Jr., in Kansas City, Missouri.

Harrison M. Dixon, 82, whose career as an agricultural economist with the U. S. Department of Agriculture spanned the years 1911 to 1956, died in December 1970. He was director of agricultural economics programs for the Federal Extension Service when he retired in 1956. He joined the Extension Service in 1922 and was instrumental in initiating agricultural outlook extension work in 1924. During World War II he had a major role in conducting the USDA emergency farm labor program.

Mr. Dixon was vice-president of the American Farm Economic Association in 1936. From 1939 to 1941 he was chairman of a committee appointed by AFEA on farm management terminology.

A son, Richard, of New Orleans, and a daughter, Mrs. Robert Goelz of Orinda, California, survive.

Garret L. Jordan, professor emeritus of the University of Illinois, died in November 1969 at age 73. Dr. Jordan had served the University from 1927 until his retirement in 1960. During this period he served as assistant to the Dean of the College of Agriculture from 1929 to 1938 and twice served as acting head of the Department of Agricultural Economics. Born in Whitley County, Indiana, he received his B.S. degree from Purdue University and M.A. and Ph.D. degrees from the University of Illinois. Prior to joining the staff at Illinois, he did banking and farm credit work in Indiana and Florida.

Dr. Jordan was active in research and teaching in price forecasting and marketing. During his long service on the Illinois faculty, he taught hundreds of students in his classes on agricultural finance, prices, statistics, and marketing. He specialized in commodity futures; he published widely in the field and served as a private consultant after his retirement.

Jim F. Tomlinson, assistant professor in the Department of Agricultural Economics at Oklahoma State University, died in November 1970. Born in Elk City, Oklahoma, in 1905, he received the B.S. and M.S. degrees from Oklahoma State University. His widow and four sons survive.

Prior to joining the faculty in agricultural economics at Oklahoma State in 1956, Professor Tomlinson taught vocational agriculture in Oklahoma, was head of the agricultural department at Cameron College, and was farm coordinator for the Oklahoma Agricultural Experiment Station. His contributions to agriculture were many and varied. Perhaps his outstanding contribution was the development of agricultural production packages involving new research results. This work greatly expedited and accelerated introduction of new technology into farming systems.

DOCTORAL DEGREES CONFERRED IN AGRICULTURAL ECONOMICS, 1970

UNIVERSITY OF CALIFORNIA, BERKELEY

Giorgio Cingolani, Graduate, Catholic University of the Sacred Heart, Milan, Italy, 1959; M.S. University of California, 1964; Ph.D. *Analysis of the Dynamics of Treefruit Acreage in California's Central Valley.*

Richard S. Johnston, A.B. Washington State University, 1960; Ph.D. *The Growth of Firms in Some Food Marketing and Processing Industries.*

Tatsuo Kobayashi, B. A. Beloit College, 1957; M.S. University of Missouri, 1959; Ph.D. *The Land Reform in Japan.*

Richard J. Marasco, B.S. Utah State University, 1965; M.S. Utah State University, 1966; Ph.D. *The Organization of the California Tuna Industry: An Economic Analysis of the Relations Between Market Performance and Conservation in the Fisheries.*

Timothy Mount, B.Sc. University of London, 1963; M.S. Oregon State University, 1964; M.A. University of California, 1967; Ph.D. *An Analysis of Production Behavior Incorporating Technical Change.*

Rodrigo Mujica, Graduate, Catholic University of Chile, 1965; M.S. University of California, 1966; M.A. University of California, 1967; Ph.D. *Satiation Levels and Consumer Demand: Analysis of a Chilean Family Expenditures Survey.*

Gholamreza Soltani-Mohammadi, Graduate, University of Tehran, 1964; M.S. University of California, 1967; Ph.D. *Efficient Development of*

Irrigated Agriculture in Iran: The Problem of Choice Between Irrigation Techniques.

Gail Eric Updegraff, B.S. Ohio State University, 1965; M.S. Iowa State, 1967; Ph.D. *The Economics of Sewage Disposal in A Coastal Urban Area: A Case Study of the Monterey Peninsula, California.*

UNIVERSITY OF CALIFORNIA, DAVIS

Nazmi Demir, Graduate, University of Ankara, 1962; M.S. University of California, 1967; Ph.D. *Input-Output Projections (1975, 1980, 1985) of California Resource Requirements with Emphasis on Technological Change.*

Russell Lynn Gum, M.S. University of California, 1964; Ph.D. *Analysis of Factors Influencing the Use of State and Federal Outdoor Recreation Sites in the West.*

Andrew Desmond O'Rourke, A.B. Queens University, Belfast, 1960; B. Comm. National University of Ireland, 1963; M.S. University of California, 1968; Ph.D. *California Fresh and Frozen Fish Trade.*

CLEMSON UNIVERSITY

Eugene Anderson Laurent, B.S. University of Georgia, 1965; M.S. University of Nebraska, 1967; Ph.D. *Economic-Ecologic Analysis in the Charleston Metropolitan Region: An Input-Output Study.*

UNIVERSITY OF CONNECTICUT

Shirley Collins Browning, B.S. University of Kentucky, 1964; M.S. University of Kentucky, 1967; Ph.D. *Analysis of the Optimum Carryover Level for Grains in Relation to Foreign Aid Requirements.*

Harold Garth Coffin, B.Sc. McGill University, 1962; M.S. University of Connecticut, 1967; Ph.D. *An Economic Analysis of Import Demand for Wheat and Flour in World Markets.*

Andrew Anton Duymovic, B.S. Cornell University, 1962; M.S. University of Connecticut, 1967; Ph.D. *The Effect of Income Transfers on the Distribution of Income in the United States.*

CORNELL UNIVERSITY

Allen Clifford Bjergo, B.S. North Dakota State University, 1962; M.A. New Mexico State University, 1964; Ph.D. *A Study of Decision-Making in Twenty-One New York Farm Families.*

Terry Lynn Crawford, B.S. New Mexico State University, 1966; M.S. Cornell University, 1968; Ph.D. *Managing a Data Information System.*

Muhammad Osman Farruk, B.A. University of Dacca, 1961; M.A. University of Dacca, 1962; M.S. Texas A&M University, 1965; Ph.D. *Structure and Performance of the Rice Marketing System in East Pakistan.*

Paul Hayden Gessaman, B.S. Montana State University, 1966; M.S. Montana State University, 1967; Ph.D. *A Study of the Impact of Transportation on Land Use and Rural Life in Four Southern Tier Counties of New York.*

Timothy Merrill Hammonds, B.S. Cornell University, 1966; M.B.A. Cornell University, 1967; Ph.D. *Utilization of Protein Ingredients in the U. S. Food Industry.*

Peter Brian Reginald Hazell, C.D.A. and N.D.A. Seale-Hayne Agricultural College, 1964; C.D.F.M. Seale-Hayne Agricultural College, 1965; M.S. Cornell University, 1968; Ph.D. *Rational Decision Making and Parametric Linear Programming Models for Combining Farm Enterprises Under Uncertainty.*

Lawrence Winthrop Libby, B.S. University of Maine, 1962; M.S. Cornell University, 1968; Ph.D. *The Political Economy of Water Management: Conceptual Model and Decision Strategy for the Susquehanna Basin.*

Donald MacLaren, B.Sc. Aberdeen University, 1966; M.S. Cornell University, 1968; Ph.D. *Agriculture and the Trade Balance of the United Kingdom: A Theoretical and Econometric Analysis.*

Thomas David McCullough, B.Sc. University College, Dublin, 1961; M.S. Virginia Polytechnic Institute, 1967; Ph.D. *Unit Pricing in Supermarkets: Alternatives, Costs and Consumer Reaction.*

Richard Lee Meyer, B.S. University of Minnesota, 1959; M.S. Cornell University, 1967; Ph.D. *Debt Repayment Capacity of the Chilean Agrarian Reform Beneficiaries.*

Mohammad Raquibuzzaman, B.A. University of Dacca, 1963; M.A. University of Dacca, 1964; Ph.D. *An Economic Appraisal of the Sugar Policies of Developed Countries and the Implications of these Policies to Developing Nations.*

Vishnoo Prasad Shukla, B.Sc. Agricultural College, Nagpur, 1949; M.A. Saugor University, Jabalpur, 1951; L.L.B. Saugor University, Jabalpur, 1952; M.S. University of Illinois, 1961; Ph.D. *An Economic Analysis of Resource Use in Farming, Jabalpur District, Madhya Pradesh, India, 1967–68.*

Louis John Wilkerson, B.S. Utah State University, 1965; M.S. Cornell University, 1967; Ph.D. *Factors Influencing Consumers Acceptance of Fluid Milk Substitutes.*

UNIVERSITY OF HAWAII

Herbert K. Marutani, B.B.A. University of Hawaii, 1953; M.S. University of Illinois, 1958; Ph.D. *Labor-Management Relations in Agriculture: A Study of the Hawaiian Sugar Industry.*

Hong Keun Sohn, B.C. Seoul National University, 1961; M.B.A. University of Hawaii, 1967; Ph.D.

A Spatial Equilibrium Model of the Beef Industry in the United States.

UNIVERSITY OF ILLINOIS

Eldon Dean Baldwin, B.S. Ohio State University, 1963; M.S. University of Illinois, 1967; Ph.D. *Optimal Market Structure Adjustments to Field Shelling of Corn.*

Peter James Barry, B.S. University of Illinois, 1963; M.S. University of Illinois, 1964; Ph.D. *Reservation Prices on Credit Use Over Time: Implications for Growth of Cash Grain Farmers.*

Suresh Chandra Birla, B.S. Madhya Bharat College of Agriculture, 1954; M.S. Government Agricultural College, Kanpur, 1957; Ph.D. *Regional Demand Analysis of Major Foodgrains in India.*

William Gustav Bursch, B.S. University of Minnesota, 1969; M.S. University of Minnesota, 1966; Ph.D. *An Analysis of Selected Aspects of Differential Pricing in Illinois Retail Feed Markets.*

Ramon Jansuy Cruz, B.S. University of the Philippines, 1959; M.S. University of the Philippines, 1963; Ph.D. *Measuring Disguised Unemployment by Means of Labor Norms.*

Thomas Lee Frey, B.S. University of Illinois, 1958; M.S. University of Illinois, 1959; Ph.D. *Optimal Asset and Liability Decisions for a Rural Rank: An Application of Multi-Period Linear-Programming.*

Georges Louis Julien Honhon, Ingenieur Agronome, University of Louvain, 1963; M.S. University of Illinois, 1969; Ph.D. *An Econometric Analysis of the Corn Market in an Open Economy.*

Jaswant Rai Jindia, B.S. Ripudaman College, 1950; M.S. University of Illinois, 1968; Ph.D. *Estimation of Costs and Returns on Indian Farms—Sampling Problems and Production Function Analysis.*

Paul William Lytle, B.S. Ohio State University, 1965; M.S. Ohio State University, 1967; Ph.D. *An Economic Analysis of the Optimum Combination of Resources Among and Within Illinois Country Elevators.*

Rama Shanker Misra, M.S. Kanpur Agricultural College, 1951; M.S. University of Illinois, 1963; Ph.D. *Production and Market Potentials of Soybeans in India.*

Shridhar Prasad Pant, B.S. Agra University, 1945; M.S. Agra University, 1948; Ph.D. *An Evaluation of Econometric and Mathematical Programming Models Useful for Planning the Agricultural Sector in India.*

Gentil Rojas, B.S. Universidad Del Valle, 1964; M.S. Ohio State University, 1965; Ph.D. *An Integrated Approach for Planning Optimum Farm Production, Marketing and Financial Choices in the Caucas Valley of Colombia.*

James Dwight Sullivan, B.S. Ohio State University, 1965; M.S. Ohio State University, 1966; Ph.D. *Interregional Flows of Slaughter Cattle, Carcass, Primal, and Retail Beef in the United States.*

James Alton Wells, B.S. University of Kentucky, 1949; M.S. University of Kentucky, 1951; Ph.D. *Economic Analysis of Fluid-Mixed Fertilizer Plants in the Midwest Area of the United States.*

Ian Robert Wills, B.S. University of Melbourne, 1962; M.S. University of Melbourne, 1965; Ph.D. *The Implication of the Green Revolution for Future Production Income and Employment in Agriculture in Western Uttar Pradesh, India.*

IOWA STATE UNIVERSITY

Mohamed Hassan Askalani, B.S. Cairo University, 1961; Ph.D. *Economic Analysis and Alternative Procedures for Estimating Broiler Production Functions.*

Andrew Gerard Conway, B. Agr. Sc. National University of Ireland, 1961; Ph.D. *An Operational Model of the Relationship Between Liveweight Gain and Stocking Rate for Grazing Cattle, With an Estimated Production Function for Steers, Under Irish Conditions.*

Bhaarat Prasad Dhital, B.Sc. Poona University, 1960; M.Sc. Indian Agricultural Research Institute, 1963; Ph.D. *Role of Agriculture in Economic Development in Nepal.*

Roger Karton Eyvindson, B.S.A. University of Manitoba, 1960; M.S. University of Manitoba, 1961; Ph.D. *A Model of Interregional Competition in Agriculture Incorporating Consuming Regions, Producing Areas, Farm Size Groups and Land Classes.*

Walter Werner Haessel, B.Sc. University of Alberta, 1964; M.Sc. University of Alberta, 1966; Ph.D. *A Theoretical Analysis of Intersectoral Relationships in a Five-Sector, Optimizing Model of a Dual Economy.*

Donald William Lybecker, B.S. Washington State University, 1961; M.A. Washington State University, 1963; Ph.D. *Optimum Resource Use in Irrigated Agriculture: Comarca Lagunera, Mexico.*

Robert Lee Oehrtman, B.S. The Ohio State University, 1961; M.S. Oregon State University, 1964; Ph.D. *A Hierarchical Factor Analysis of the Adjustment Problems Facing Milk Bottling Firms.*

Edmond Eggleston Seay, Jr., B.S. Virginia Polytechnic Institute, 1953; M.S. Cornell University, 1958; Ph.D. *Minimizing Abatement Costs of Water Pollutants From Agriculture: A Parametric Linear Programming Approach.*

Ronald W. Ward, B.S. University of Tennessee, 1965; M.S. Iowa State University, 1967; Ph.D. *Some Theoretical Considerations for Futures Trading in Commodities Requiring Transformation Services: The Case for Live Beef Futures.*

Gaylord Edsel Worden, B.S. Iowa State University, 1959; M.S. Iowa State University, 1965;

Ph.D. *An Interfirm Competition Model for Deriving Empirical Estimates of Supply Response.*

UNIVERSITY OF KENTUCKY

Richard F. Bieker, B.A. Murray State College, 1966; Ph.D. *Social and Economic Determinants of the Educational Achievement of Selected Eleventh Grade Students in Rural Kentucky—An Exploratory Study.*

James M. Conrad, B.S. 1964, M.S. 1965, Purdue University; Ph.D. *An Economic Analysis of the Impact of a New College on a Rural Community.*

Raymond D. Humberd, B.S. 1959; M.S. 1965, University of Tennessee; Ph.D. *A Multiperiod Analysis of the Effect of Selected Economic Variables on the Optimum Growth Process of Three Case Farms in the Mammoth Cave Area.*

Larry C. Jenkins, B.S. 1961, M.S. 1965, University of Missouri; Ph.D. *Adjustment Responses of Northwestern Kentucky Commercial Farmers to Changes in Cost and Availability of Resources.*

James W. Middleton, B.A. University of Kentucky, 1966; Ph.D. *The 1965 Property Revaluation in Fayette County, Kentucky.*

LOUISIANA STATE UNIVERSITY

Arthur Raymond Gerlow, B.S. Louisiana State University, 1950; M.S. Louisiana State University, 1954; Ph.D. *Resource Adjustments Necessary for Income Maximization on Farms in the Southwest Louisiana Rice Area.*

Gerald G. Giesler, B.S. University of Missouri, 1963; M.S. University of Missouri, 1965; Ph.D. *An Economic Analysis of the Effect of Cattle Prices, By-Product Prices and Plant Location on the Louisiana Slaughter Industry.*

Richard H. Jesse, B.S. Southern Illinois University, 1964; M.S. Southern Illinois University, 1965; Ph.D. *Number, Size, and Location of Processing Facilities for More Efficient Marketing of Louisiana Cotton.*

Lynn A. Stanton, B.S. Cornell University, 1959; M.S. Cornell University, 1961; Ph.D. *Comparison of Selected Linear Programming Techniques for Planning Farms Using Louisiana Farm Business Analysis Records.*

UNIVERSITY OF MARYLAND

Discrimination in the Markets for Farm Capital?*

ROBERT TINNEY AND FINIS WELCH

Recent empirical investigations have estimated differential earnings of white and nonwhite labor and education and have interpreted these differences as the combined effects of many forms of economic discrimination. In this paper we use a relatively straightforward model to analyze the implications of discrimination in markets for capital funds. The model is designed to focus upon intermarket flows of goods, in this case white to black, and represents a simple modification of the common excess demand and supply frame of reference. The empirical evidence suggests that earned rates of return do not vary with the race of farm operators as most "theories" of discrimination would suggest. However, there is evidence that rates of return increase with farm size, and since Negroes operate smaller farms it is possible that discrimination has served as an impediment to expansion.

THERE SEEMS to be a popular consensus that in all phases of life there is discrimination against the American Negro. He is presumed to be penalized when he sells his services as a laborer, when he purchases factors and sells products as a producer, when he rents or buys housing, when he attends school, when he attempts to borrow money, and so on, throughout the sphere of his economic and extra-economic activities. Never has a thorough understanding of the processes of discrimination been more relevant than today. If remedial measures are to be undertaken, discriminatory mechanisms must be understood and their impact identified so that a scheme of priorities can be specified. Some piecemeal and stopgap measures in use today are likely to be inefficient and perhaps are ineffective, and analyses of this type can help to reorder priorities for remedial measures.

In recent years we have made considerable progress in developing a taxonomy that permits a fuller understanding of the ramifications of economic discrimination. The pathbreaking work in the area was that of Gary Becker [1], who pointed out the implications of a "taste for discrimination" and made us aware that not only will discrimination cost those discriminated against, but, barring universal collusion, it will also cost the discriminators. One result of Becker's taxonomy is that in many instances one is hard pressed to explain the existence of discrimination in a reasonably competitive market. For example, how can there be discrimination in housing if possibilities for new construction are available? Too, if there is discrimination in loan markets, why would anyone interested in maximizing revenue loan money to whites when Negroes are willing to borrow at higher interest rates? And would we not expect this propensity to loan to Negroes to force interest rates charged to Negroes and whites toward equality? Here, in order to "explain" differentials among Negroes and whites, it is usually necessary to introduce the idea of the psychic discount. A (white) person will not loan funds at equal rates to Negroes and whites, nor will he sell (or rent) a house at the same price if there are psychic costs involved in associating with Negroes. However, as Welch has indicated [9], the use of psychic discounts to explain price differentials makes it necessary to distinguish between personalized and impersonal products or services. As an example, it is easy to see how there can be discrimination against labor services since these cannot be divorced from the laborer providing them. But it is not easy to understand discrimination against an impersonal product. How meaningful is a psychic discount if the producer of a product cannot be identified? Thus, Welch has pointed out that when the product (or factor) is impersonal, any psychic discount must be attributed to association between buyer and seller during the time the product is being transferred. Since the product is impersonal, the seller's race is not an intrinsic characteristic and is irrelevant after the transaction has occurred. For this reason a discount in the value of an impersonal product (because of nonpecuniary costs occurring during the transaction) introduces the possibility of intermediation.

Although in this case the role of the intermediary is obvious, it is convenient to specify his function somewhat more formally, since in doing so we will provide the format for the

* We are indebted to our reviewers, Jim Seagraves and Emanuel Melichar. Support for this project was provided by the Rockefeller Foundation and NBER. The article has not been submitted for review to NBER.

ROBERT TINNEY *is with the Pennsylvania State University.* FINIS WELCH *is with the National Bureau of Economic Research.*

analysis used in this paper. Let us suppose that a Negro sells an impersonal product to a white for a price of P and that, because of the psychic costs involved, he acts *as if* he has received only $P(1-\pi_s)$, where $P\pi_s$ is the equivalent monetary value of the seller's psychic discount. Furthermore, assume that the buyer who pays price P acts as if the price is actually $P(1+\pi_b)$, where $P\pi_b$ is the monetary equivalent of the buyer's psychic cost. Now the mutual discrimination drives a wedge between the consumer's and producer's effective prices that is simply the sum of the monetary equivalent discounts, $P(\pi_s+\pi_b)$. It is possible that π_s can be zero if the seller is indifferent toward the buyer, or even negative if he views the buyer "charitably." The same may be true of π_b with respect to the buyer's attitude toward the seller; nevertheless, we assume that the sum of $\pi_s+\pi_b$ is positive. In this case, suppose that an intermediary appears. If he can effect the product's transfer between seller and buyer at a cost lower than $P(\pi_s+\pi_b)$, he will find it profitable to do so.[1] Even in the absence of discrimination most products require intermediation as a normal market function in circumventing barriers of distance and information. Because of this it is likely that the process of providing a buffer between antagonistic buyers and sellers may not increase normal transaction costs. This would be especially true if there were a relatively large supply of persons who neither affect nor are affected by those with whom they trade. Such persons have a comparative advantage as intermediaries and, if their supply is large enough, their characteristics are prerequisite to employment as an intermediary.

All of this implies that discrimination against the producers of impersonal products may be less likely than is commonly assumed. The potential for discrimination may be more important in determining the characteristics of "middlemen" than in increasing the spread between producer and consumer prices. But the same is true of impersonal factors of production, and that is why we are somewhat dubious about asking the question: Is there discrimination in the supply of funds to Negro farm operators?

The Basic Model

We begin with a fully democratic model of interacting discrimination between suppliers and borrowers of capital funds. The model is democratic in the sense that both Negroes and whites are potential discriminators. We assume that at any given interest rate, some Negroes and whites will be lenders while others of each group will be borrowers. Whether a particular individual is a borrower or a lender will depend upon his subjective evaluation of the marginal productivity of capital used on his farm, the market rate of interest, and the "asset position" of the farmer. If the market permits him to loan some of his funds at a higher rate of return than he believes he can earn by using them himself, the presumption is that he will lend and that if conditions are reversed, he will be a borrower.

Because of the possibility of discrimination, it is not obvious a priori how supply and demand functions should be specified. The problem arises inasmuch as the level of demand is affected at least potentially by the race of the seller and the level of supply is affected by the buyer's race. To avoid these ambiguities we specify demand and supply functions separately for Negroes and whites on the assumption that transactions are intraracial; and when transactions are interracial, we explicitly consider shifts in the respective demand and supply functions. Thus, in this pseudo-segregation of the market, the demand function of whites is presumed to carry the interpretation that it represents a schedule of quantities demanded at given interest rates ***when the capital is supplied by whites***. Similarly, the white supply schedule connotes "supplied to whites," just as the Negro demand and supply schedules refer to transactions within the "Negro market" only.

Discrimination is introduced as a shift in a particular demand or supply schedule. If white borrowers have a relative preference for funds borrowed from whites, they are presumed to act as though funds borrowed from Negroes are obtained at higher interest charges than they actually are. This relative preference can be expressed as a downward shift in the white demand functions as viewed by Negro suppliers. It follows that if white suppliers have a relative preference for lending to whites, they will act as if interest payments received from Negroes are lower than they are in fact. Such a reaction is expressed as an upward shift in the supply of white capital as viewed by Negro borrowers. The discriminatory mechanism is fully operable once the possibility of Negro discrimination against whites is added. We assume simply that

[1] Notice that the intermediary's cost will include any psychic discount resulting from his association with the buyer and seller, regardless of which participant is affected.

as viewed by whites, respectively demanders and suppliers, the supply function of Negro capital lies above its segregated market equivalent and the demand function of Negroes for capital lies below its equivalent in the Negro market.

Given the potential for discrimination on the part of all suppliers and demanders, in order to determine the market's equilibrium it is necessary to realize that if discrimination does in fact exist, funds will not flow simultaneously from the white to the Negro market and from the Negro to the white market. If whites lend to Negroes, we assume that the interest rate paid by Negro borrowers must be sufficiently greater than the rate paid by whites so that suppliers can be compensated for their psychic costs. It also follows that if Negro demanders discriminate against whites they will pay lower rates for funds supplied by whites than for funds supplied by Negroes. Thus, if whites lend to Negroes, Negroes will not lend to whites since the interest rate they can receive from Negroes will exceed that offered by white borrowers.

In Figure 1 we have depicted a market for capital funds in which both whites and Negroes are (potential) discriminators. Since in the presence of discrimination we would not expect funds to be loaned simultaneously by whites to Negroes and by Negroes to whites, we have initially assumed an artificial segregation of the market into white and black components, parts (a) and (b), respectively, in Figure 1. Assuming that whites will supply funds to Negroes, we derive an excess demand function of Negroes for funds and an excess supply function of funds from whites, part (c) in Figure 1. More specifically, part (a) indicates the segregated white market with demand D_w and supply S_w. If the markets were fully segregated, the equilibrium interest rate in the white market would

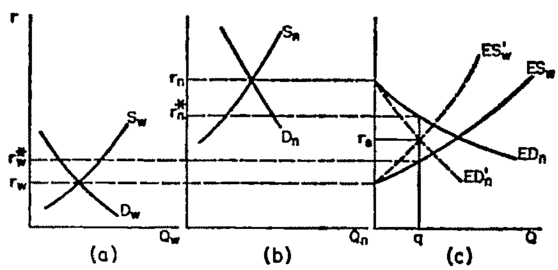

Figure 1. A hypothetical specification of discrimination in a market composed of two groups in which some members of each group are suppliers and demanders

be r_w. Similarly, in part (b), D_n and S_n indicate the respective demand and supply functions for the Negroes with a segregated equilibrium interest rate, r_n. Since by assumption r_n exceeds r_w, if the market is integrated whites will lend to Negroes.

Two steps are required to derive the supply of funds loaned to Negroes by whites. First, we ignore discrimination and consider the quantity of funds that would leave the segregated white market at each interest rate. That quantity is positive only for rates in excess of r_w and is given as $ES_w = S_w - D_w$, i.e., the excess quantity supplied over that demanded at each interest rate. The second step provides for discrimination by white suppliers by introducing an upward shift in the excess supply function from ES_w to ES_w'. The demand of Negroes for white funds is obtained in a similar manner. An excess demand function is derived from the segregated Negro market and then shifted downward from ED_n to allow for discrimination by Negro demanders. At the quantity q in part (c) the integrated market attains an equilibrium. There are now three equilibrium interest rates, r_w^* for whites borrowing from whites, r_n^* for Negroes borrowing from Negroes, and r_e for Negroes who borrow from whites. Each is an equilibrium since a Negro who borrows from a white at a rate of r_e will behave as though the rate were r_n^* and whites who supply funds to Negroes at r_e act as if they receive only r_w^*.

The Empirical Specification

We assume that farm operators employ just enough capital so that the rate of return earned on the farm is equal, at the margin, to the market rate of interest. This follows from a joint assumption that farmers are maximizing profit (or their psychic equivalent) and that within each segregated market, the interest rate is the same for borrowing and lending and is therefore both the explicit cost of capital for borrowers and the implicit or opportunity cost for those who use their own capital. An added assumption is that the capital market is integrated, with whites lending to Negroes. Thus, in the presence of discrimination there is a difference in the cost of capital as viewed by Negro and white farm operators, and the interest rate used for decisions by Negro farm operators will exceed the rate used by white farmers. (In Figure 1 these rates are r_n^* and r_w^*, respectively.) It follows that by observing earned rates of return on farm capital we can, at least in principle,

"test" for the presence of discrimination. For example, if the earned rate of return on capital employed by Negro operators exceeds that of whites, there may be discrimination in farm capital markets; but if there is no difference in earned rates of return, the implication is that there is no discrimination.

It is important that an observed difference in rates of return is interpreted as the combined effect of discrimination by borrowers and lenders and cannot be construed as evidence that one particular group or race is discriminating against another. Evidence of discrimination by lenders belonging to a specific group must be obtained directly by comparing the rates at which persons in that group loan to other members of their group and to persons of other groups. Likewise, evidence of discrimination by borrowers requires observation of the relationship between the borrowing rate and the lender's race.

In this paper rates of return earned by Negroes and whites on capital invested on farms are taken from regression estimates of the rate of return earned on operator-owned farm land and buildings.

The data used are taken from a matched sample of the 1960 Sample Survey of Agriculture [6] and the 1960 Census of Population [7]. The matched sample contains detailed information on 1,929 farm operator families who were selected on the basis of a stratified sample in which the sampling frequencies increase with farm size. The sampling ratios ranged from 1 in 9,999 on the smallest farms to 1 in 548 on the largest. Within the sample there are 733 farm operators in the South Atlantic, East South Central, or West South Central agricultural divisions who were 25 years old or over in 1960, who did not have an urban residence, who were characterized as either Negro or white (other nonwhites eliminated), and who had worked sometime during the last decade. Our analysis is restricted to these persons. They include 132 Negro and 601 white farmers, of whom 60 Negroes and 496 whites own some of the land on their farm. Among Negroes who own land the average value of land and buildings owned is $6,300; for whites the corresponding value is $21,500.

Other relevant characteristics of the sample population—the distribution of operator-owned land and buildings, the distribution of years of school completed, and the age distribution—are provided separately for Negro and white farm operators in Appendix Table A. To estimate earned rates of return on farm capital we have used an accounting definition of income in which business income[2] is viewed as the sum of the income to the operator's labor and the return to his invested capital.

The return to capital is considered as the average rate of return times the capital value.[3] The return to the operator's labor is assumed to be a function of his schooling and its quality, his age, and other variables.

The preceding analysis is couched wholly in terms of discrimination that results in a difference in the earned rate of return between Negro and white farm operators. It is important that returns to capital may vary, not only between races, but because of economies of scale and other transitory conditions permitting windfall profits or quasi-rents that may be correlated with capital investments. If rates of return decrease with farm size, there is no analytical problem. The type of discrimination described here simply results in Negro-owned farms whose most efficient size is smaller than it would otherwise be, and these farms will have a higher "equilibrium" rate of return. On the other hand, if rates of return increase with size, disscrimination may serve as an impediment to expansion. Farm sizes in which the marginal productivity of capital is increasing are not efficient unless marginal capital costs are increasing even more rapidly; otherwise it will "pay" firms to expand and exhaust scale economies. But suppose that, because of discrimination, the supply price of funds to Negroes is above the maximum rate of return that can be earned at any farm size. Discrimination of this type amounts to a refusal to loan. Now suppose that there are in essence two capital markets—one formal, the other informal. In the informal market funds are obtained from family, friends, and perhaps government agencies (Farmers Home Administration) at subsidized rates. If the formal market excludes Negroes because of

---

[2] The Census defines total income as the sum of wage and salary income, business income, and other income. The definition of wage and salary income is obvious. Business income is the combined return to labor supplied by the entrepreneur and the return to his capital invested in the business. Other income includes transfer payments and income to capital not invested in a firm operated by its owner.

[3] The return to capital of value C is sometimes defined as $R=(r+\delta)C$ where r is the net rate of return and δ is the rate of depreciation. (If the value of capital has appreciated, δ will be negative.) Our estimates are of gross rather than net rate of return.

a prohibiting charge and the only access to funds is through informal markets, we would have no a priori reason to expect any relationship between realized rate of return and the race of the farmer, over all scale classes; but we would expect that within each class nonwhites would earn higher rates of return as they substitute other inputs for the relatively scarce capital. Bear in mind that rates of return increasing with farm size are prerequisite to this sort of discrimination.

The explicit form of the income equation is given as

$$Y = r_{ij}C + S_{ik} + A_l + R_m + T + u$$

where

Y is business income in 1959.

C is the estimated value of operator-owned farm land and buildings.

r_{ij} is the average rate of return on owned land and buildings earned by farm operators of the ith race, Negro or white, and the jth farm scale class. Three scale classes are used: (1) commercial farm (sales in excess of $5,000; classes for larger farms were not specified because there are very few Negroes in the sample with sales exceeding $5,000); (2) small farm (sales less than $5,000 but not a part-time farmer); (3) part-time farmer (sales less than $2,500 and 100 or more days worked off the farm in 1959). Notice that with the race-scale interaction there are six separate rates of return to be estimated.

S_{ik} is the predicted income of a person (who is 45–54 years old, lives in the South Atlantic division of the South, and is not a "cropper") who is of the ith race and the kth schooling class and owns no land or buildings. The schooling classes refer to years of school completed and correspond to 0–4, 5–11, 12–15, and 16 or more years of school completed. There are no Negroes in the sample who have completed 16 or more years. The interaction between race and schooling (providing 7 distinct coefficients, 4 for white schooling and 3 for Negro) is required because of the possibility of quality differences in Negro and white schooling.

A_l is an adjustment in predicted income for persons who are not 45–54 years old. For the lth age class (there are five, 24–34, 35–44, 45–54, 55–64, and 65 or more) A_l is interpreted as the change in income as the operator's age changes from 45–54 to that of the lth class.

R_m is an adjustment in predicted income for persons who do not live in the South Atlantic region (there are two others, East and West South Central). Regional coefficients are estimated as an allowance for transitory phenomena that are regionally correlated, such as weather. The use of a single year, 1959, for the income observation requires allowances for transitory components in income.

T is an adjustment in predicted income for persons who are neither full nor part owners of the farms they operate, i.e., who are croppers or other tenants. A cropper is a tenant who works under a crop-share contractual arrangement. For a given share agreement to be viable, it must result in the long run in operator (and landlord) income similar to that resulting from ownership or other tenant arrangements. Yet, in any given year the inflexibility of the contract may result in windfall losses or gains for the farm operator. In the long run the average windfall should be zero.

u is an unobserved measure of the individual characteristics that affect a person's income and are not caught in the above crude measures.

Although this particular functional form is obviously designed for tests of hypotheses about the alternative values of r_{ij}, it is important to be aware that such tests are severely limited in terms of their general validity. As we see it, there are two major shortcomings. The first is that the model refers to only one year, 1959. For residual income recipients, such as farm capital, there are likely to be considerable transitory components in realized rates of return, so that observations for a single year may be subject to large biases. That these transitory phenomena would be correlated with the race of the farm operator appears to be unlikely; but we would nevertheless prefer evidence for several periods with more fluctuation in "other things." The second major disadvantage is that the functional specification is designed to estimate *average* rates of return over large intervals. The "theory" of the earlier section is couched wholly in terms of marginal rates of return. We

do not have adequate information about the relationship between marginal and average returns for farm capital; so, in the absence of an alternative, we selected this simple form which implies equality between the average and margin. Again, divergence between average and marginal rates of return can bias our results.[4] On the plus side, implicit evidence of this type, taken directly from observations of income and the ownership of capital, is net of risk and related adjustments and is therefore not subject to biases that would ordinarily thwart direct comparisons of loan markets.

The Results

The equation specified above is first estimated and used as our maintained hypothesis that earned rates of return to farm capital vary both with the race of the farm operator and the scale of the farm. Against this we test the alternatives that rates of return vary neither by race nor by scale, that they vary by scale class but not by race, and that they vary by race but not by scale class. Estimates of the maintained (equation 1) and alternative hypotheses (equations 2–4) are provided in Table 1. Notice that the maintained hypothesis allows for six distinct estimates of rates corresponding to the three scale classes for each of the two specifications of operator's race. In comparison, under the alternative hypotheses fewer rates are estimated as various constraints are imposed.

In the regression equation 1, estimated rates of return earned by Negroes exceed those earned by whites in the two scale classes corresponding to the largest farms. This is, of course, consistent with discrimination in capital markets, but a question of the significance of these differences remains. Regression equation 2 imposes the constraint that within each of the scale classes Negroes and whites earn the same rate of return. Equation 3 allows for differences in rates of returns by race but constrains the estimates so that returns do not vary by scale, and equation 4 permits the estimated rate of return to vary neither by scale class nor by the race of the operator.

To "test" for the existence of either race or scale effects, equation 4 is compared with equation 1. The comparison yields a computed $F(5,713)=2.31$ with associated 0.05 critical value of 2.22. Thus, there is weak support for the hypothesis that rates of return vary either by scale class or by race, or by both. To see whether the difference can be described as "scale only" or "race only," equations 3 and 2 are then also compared with equation 1.

The comparison of 3 with 1 yields a computed $F(4,713)=3.33$ with associated 0.05 critical value 2.38. Thus, we cannot accept the hypothesis imposed by equation 3 that rates of return are independent of farm scale. Alternatively, the comparison of equation 2 with 1 yields a computed $F(3,713)=0.16$ with 0.05 critical level 2.61 so that the hypothesis that rates of return, within each scale class, are the same for Negroes and whites is accepted. Equation 2 is therefore our best estimate.

The evidence is that rates of return vary with farm size and that they increase as size increases. Negroes earn lower returns than whites, not because returns differ within scale classes, but because Negroes operate smaller farms. Is this evidence of discrimination? The answer is a somewhat timid "No, but discrimination is consistent with the observation." Strong evidence of discrimination requires evidence of Negroes earning higher returns than whites. If returns increased with farm size and capital were more of an inhibiting factor for Negroes (i.e., there is discrimination) in their attempts to expand, we would expect to see Negro operators "pushing harder" against the capital constraint, that is, earning higher returns within size classes. This evidence is missing. On the other hand, the evidence is consistent with an hypothesis of no discrimination, but this interpretation presents the question of why Negro farms have not attained the same "size" as white farms. What we can conclude is that the market has not operated to permit an observation of the kind of discrimination described in the model presented earlier. This may be either because there is in fact no discrimination or because discrimination has been more "prohibiting" in the sense that charges precluded borrowing rather than being merely "slightly" higher rates. The type of data described here cannot go further in breaking into this "box," but let us speculate.

Because of intermediation possibilities we find an argument in favor of discrimination in capital markets to be unconvincing, and the data *are* consistent with this hypothesis. Why then have Negro farms not expanded to capi-

[4] Of course, if the average rate of return function has equal elasticity for Negro and white farm operators (within the appropriate intervals), then the respective marginal returns are each in the same proportion to the average. In this case, the comparisons retain their validity.

Table 1. Regression estimates of factors contributing to the business income of Southern farm operators, 1959[a]

Factor	Regression number (1)	(2)	(3)	(4)
	Race and scale specification used in equation			
	Full race-scale interaction	Scale differences only, race differences suppressed	Race differences only, scale differences suppressed	Both race and scale differences suppressed
	Rates of return to owned land and buildings (percent)

5–11	1,080 (210)	1,090 (210)	1,020 (210)	1,020 (210)
12–15	1,140 (270)	1,160 (270)	1,080 (270)	1,080 (270)

[a] The observations (733) are for individuals as reported in the matched sample. The definition of variables is straightforward, except for business income. For each observation business income is reported by income intervals, but "expanded" business income and "final weight factor" (the inverse of the sampling proportion) are also reported. In all cases the ratio of expanded business income to the final weight factor falls within the reported interval and is therefore taken as a point estimate.

[b] Standard errors are in parentheses.

talize upon scale economies? We feel that two factors are important here. First, the capital base is smaller so that loans would be made on less equity and would therefore be riskier. Second, rising land values for those with land, coupled with increasing nonfarm wage rates especially in the North, have eased exit from agriculture. Instead of expanding to capitalize on scale economies, capital gains are "cashed in" to ease entry into a nonagricultural, typically non-Southern life.

Our "best" estimate of the rate of return t

farm land and buildings in the South is 3.2 percent, which is essentially the same as the 3.0 percent rate of return realized by farmers on "owned assets" in 1960.[5]

However, as noted above, this estimated rate is gross of both depreciation and appreciation. Of the total value of land and buildings, about 32 percent is accounted for by buildings. Assuming a rate of depreciation for buildings of 5 percent annually and an annual rate of appreciation for agricultural land of 7 percent, the net rate of return to farm capital based on the estimated gross rate is 6.4 percent.

Although we find no direct evidence of discrimination in capital markets, there may be some indirect evidence in the estimated income-schooling profiles. Notice that while the income of white farm operators is sharply responsive to added schooling, the income of Negro farmers remains constant as additional schooling is acquired. *To the Negro farm operator in the South schooling is of no monetary value.* As we see it, there are two possible explanations of this phenomenon. First, there may be discrimination in farm capital markets of the type that simply prohibits loans to Negroes. Suppose that farm capital is relatively complementary to the skills acquired in school so that for schooling to be profitable the farm firm would have to be relatively capital intensive. Suppose further that Negroes are simply unable to borrow (from whites) at any price but that whites face a perfectly elastic supply. In this case we would have no prior expectation about a comparison between Negroes and whites of earned rates of return, but would expect to find that for Negroes rates of return are an increasing function of the operator's schooling. In the sample analyzed here there are insufficient observations to test this hypothesis together with those presented above.

An alternative explanation of the "flat" income-schooling profile for Negro farmers is that the skills they acquire in school are irrelevant in farming. This could be true either because of the inferior quality of the Negro schools or because of discrimination through things that are potential complements to schooling. An obvious example is that offered above: An inability to expand the firm restricts the value of schooling. We feel that the discriminatory practices of the Federal Extension Service (prior to the Civil Rights Act of 1964) may have been of even greater importance. Welch [10] has provided evidence suggesting that in agriculture the productivity of more-schooled, as compared with less-schooled persons, is related to the "innovative environment," which is assumed to be determined largely by the level of research and extension activity within a state. The evidence suggests that the more rapid is the rate of technical change, the greater will be the relative productivity of the well-educated person. One consequence of the segregation of the Extension Service may have been that of effectively isolating Southern Negroes from technical change in agriculture. In a special report by the U. S. Commission on Civil Rights [4], the potential for this isolation is made obvious.

The remaining estimated parameters are of less interest. The age-income profile suggests that, in this cross section, business income is maximized between 45 and 54 years of age. Persons 25 to 34 years old earned an estimated \$250 less than persons aged 45 to 54 (in 1959); the farm operator 35 to 44 years of age earns \$70 less; and so on for the remaining age groups. The coefficient for "croppers" indicates that in 1959 the contractual arrangement between croppers and landowners was favorable (+\$540) to the cropper. Recall that this phenomenon should be transitory and that over several years we would expect the average windfall associated with a particular institutional arrangement to be (approximately) zero. The discrepancies in business income among the three divisions are also presumed transitory but may reflect disequilibria in labor markets or other related phenomena.

Summary and Conclusions

We have attempted to provide a logically consistent mechanism for obtaining evidence of racial discrimination in farm loans. The model is simple and represents an extension of the standard excess supply and demand framework —one we feel to be useful in the analysis of a wide range of discriminatory phenomena. Our empirical evidence has several limitations, and we would have preferred more extensive evidence of earned rates of return based on more than one type of investment and on more than one year. Nonetheless, we believe that the results are suggestive.

The potential for intermediation in the presence of discrimination against impersonal products and factors raises the question: How

[5] See [5].

can discrimination exist in these markets? Our data suggest that it may not. The observed fluctuations in rates of return are certainly consistent with purely random behavior at generally accepted confidence levels. These data suggest that the investigator concerned with Negro-white income differentials in farming might well concentrate on differences in the productivity of schooling instead of capital markets.

The Relative Share of Labor in United States Agriculture, 1949-1968*

THEODORE P. LIANOS

The sources of change in the relative share of labor in the American agricultural sector are examined within the framework of neoclassical production theory. It is found that the observed decline in labor's relative share is due to the increasing capital-labor ratio adjusted for changing efficiency of factors and to the elasticity of substitution which is greater than unity. It is also found that the efficiency of capital is increasing faster than that of labor and that technological change in American agriculture has been labor-saving.

THE RELATIVE share of labor in U. S. manufacturing has been relatively constant over the past century. This relative stability was so surprising and unexpected on theoretical grounds as to cause Keynes [15] to call it "a bit of a miracle." Others have thought of this stability as an economic law of modern capitalism.[1] However, more recent studies by Solow [19], Kravis [16], and Ferguson and Moroney [9] have shown that for the postwar period the relative share of labor in U. S. manufacturing has increased. An entirely opposite picture emerges in the U. S. agricultural sector. Estimates supplied by Ruttan and Stout [18] clearly indicate that for the 1944–1957 period labor's relative share has been declining. Their estimates for the 1925–1944 period appear to vary around a mean value of 35.5, with no apparent trend; in 1925 the relative share of labor was 37.8, and in 1933 and 1944 slightly less at 36.1. Thus it appears that although in the prewar period the relative share of labor in agriculture showed a relative constancy, as in manufacturing, it has followed an opposite direction in the postwar period.

In this paper we attempt to do three things: (1) to describe the behavior of the relative share of labor in U. S. agriculture for the period 1949–1968; (2) to investigate the sources of change in the relative share of labor for the same period; (3) to compare our findings with those of other researchers for American nonagricultural industries. The analysis is performed within the theoretical framework of neoclassical theory of production and distribution.

Relative Share of Labor in American Agriculture: 1949-1968

Estimation of labor's relative share

Estimation of the relative share of labor was based on the definitional formula of the relative share, that is, $S_L = (W \cdot L)/Y$ where W = wage rate, L = man-hours, and Y = value of total agricultural output. The wage rate was measured by the composite rate per hour as reported in [21]. The labor input was measured by the number of man-hours as reported in [20]. This measure consists of labor required for all farmwork, and it includes farmers and unpaid family workers.[2] The measure of total agricultural output used includes cash receipts from farm marketings, household consumption, and net change in farm inventories, as reported in [20]. To the extent that intraindustry exchange takes place and/or that farm business buys farm inputs from nonfarm business, this measure of output includes double counting and thus leads to underestimation of the relative share of labor. The contribution of intraindustry exchange has probably been declining, primarily as a result of farm integration; thus the underestimation due to intraindustry exchange is declining. The contribution to double counting of nonfarm-farm business transactions cannot be determined. It is suggested, however, that double counting from this source may be increasing. This suggestion is based on Dovring's finding [6, p. 12] that the amount of labor input embodied in the nonagricultural output used by agriculture has remained relatively constant in the period 1920–1960. Given that the productivity of labor has increased, it follows that double counting has probably increased. Notice that the two sources of double

[2] In estimating the wage bill (W·L) farmers and unpaid family workers are assumed to receive the wage rate of hired labor as remuneration for their labor supply. Some of the problems resulting from this procedure of imputing wage earnings to farm operators and unpaid family workers are discussed by Ruttan and Stout [18, p. 61].

counting have opposite effects on the estimate of the relative share of labor.

In connection with the estimate of the relative share of labor there are two points to be stressed. First, even if the behavior in labor's relative share is not exactly as pictured in Figure 1, it is certainly declining, and this is what is important in attempting to explain the sources of change. The wage bill, according to our estimates (Appendix A), has been declining throughout the 1949–1968 period. Also, independent estimates by Fuller and van Vuuren [10, Table 5] show a declining wage bill for agricultural labor. Since the value of total agricultural output is not declining during the same period, the decline in the relative share of labor is established. Second, the estimation of the parameters that are crucial for the explanation of the changes in the relative share of labor, namely, the elasticity of substitution, capital-labor ratio, and factor productivity changes, does not depend on the estimate of the relative share of labor. In a sense the development and estimation of the model that is presented in the next section provides a check on the validity of the estimate of labor's relative share, since contradiction would arise if the model predicts positive changes and the data show negative changes. Such a contradiction does not arise in this paper.

However, in order to increase our degree of confidence in the finding that the relative share of labor has decreased dramatically throughout the period covered in this study, we have estimated labor's relative share, S_L', as the ratio of wage bill to value added. Value added (VA) has been estimated by $VA =$ total agricultural output—(farm operating expenses—expenses for hired labor—livestock expenses)—property taxes. Livestock expenses have been subtracted from the operating expenses because we do not view this item as an operating expense similar to the other items, since its effect on total output is not exhausted in the year the expenditure is made. The difference, however, on the estimate of the relative share of labor is negligible.

These two estimates of the relative share of labor (presented in the following section), one

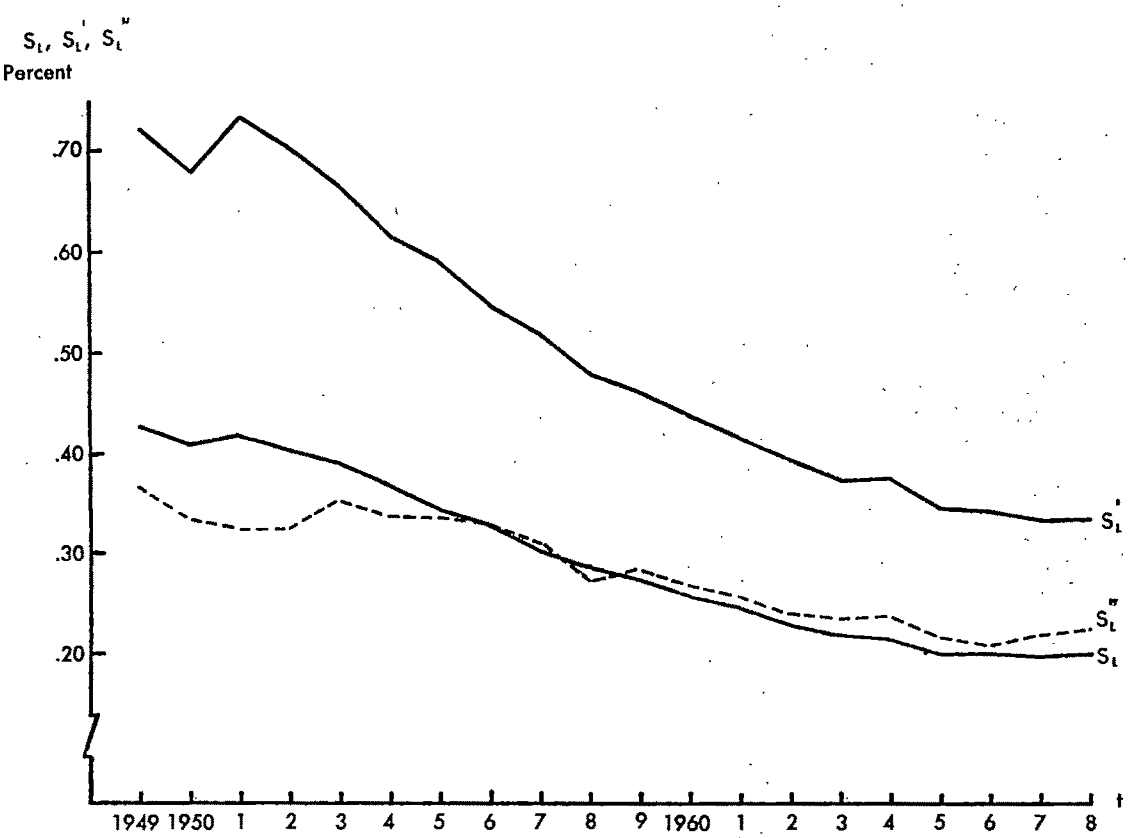

Figure 1. Relative share of labor in U. S. agriculture

based on gross output and one based on value added, were obtained by deflating wage rate estimates by the index of prices paid by farmers (1957–59 = 100) and output estimates by the index of prices received by farmers (1957–59 = 100). Admittedly this deflationary procedure is not the ideal way to transform the data into real terms, and an argument has been made for the estimation of the relative share of labor in current terms. Thus, a third estimate, S_L'', has been obtained by using money wages and by dividing the resulting wage bill by gross output in current prices. This estimate is also presented in the next section.

Behavior of labor's relative share

The estimates of the relative share of labor are presented in Table 1 and plotted against time in Figure 1. The lines labeled S_L and S_L' are based on deflated data, and the dotted line labeled S_L'' is based on data evaluated at current prices. All three measures show that the share of income allocated to labor has been declining. As expected, the use of value added rather than gross output changes the level of the relative share of labor but does not affect the direction of the changes. Use of current rather than deflated data changes the slopes of the curves only slightly. It also appears that for the last four years the relative share of labor has remained practically constant and in fact has increased when measured by S_L''. However, it is too early to assign any significance to this constancy or rise. Because the three alternative measures of the share of labor (S_L, S_L' and S_L'') show quite similar trends, an analysis of changes in shares based on any of the three series would produce similar empirical results. Only S_L will be used in the following analysis.

Table 1. Estimates of the relative share of labor and proportional change: U. S. agriculture, 1949-1968

Sources of Change in the Relative Share of Labor

Theoretical considerations[3]

Basic assumptions.—Since we are interested in aggregate magnitudes, we assume an aggregate production function with the marginal product of each factor increasing at a decreasing rate. Specifically, agricultural output is given by

$$Y = F(C, L; t)$$

where F is homogeneous of first degree in the factors of production capital (C) and labor (L). Also $F_C > 0$, $F_L > 0$, and $F_{CC} < 0$, $F_{LL} < 0$.

It is also assumed that $F_C = r$ (r = return to capital), and $F_L = W$.

Time is also included in the production function to allow for technological change. The form of F is specified later.

Bias and rate of technological change.—Using Hick's approach, the bias of technological progress is defined as the proportional change in the ratio of marginal products of capital and labor, i.e.,

$$B = \left[\frac{\partial\left(\frac{F_C}{F_L}\right)}{\partial t}\right] \div \left(\frac{F_C}{F_L}\right). \tag{1}$$

Remembering that F_C and F_L are functions of time, and after some simple manipulations, the bias is given by

$$B = \left(\frac{\partial F_C}{\partial t} \div F_C\right) - \left(\frac{\partial F_L}{\partial t} \div F_L\right). \tag{2}$$

The rate of technological progress is defined as $R = \partial F/\partial t \div F$. Remembering that F is homogeneous of degree one in the two inputs, the rate of change can be written as

$$R = \frac{\frac{\partial F_C}{\partial t}\cdot C + \frac{\partial F_L}{\partial t}\cdot L}{F}. \tag{3}$$

To express R as a function of labor's relative

[3] A clear exposition of the neoclassical theory of production and distribution which is used in this paper can be found in Ferguson [7].

share, multiply the first and second terms of the numerator of (3) by F_C/F_C and F_L/F_L, respectively. Remembering that $(F_C \cdot C)/F = S_C = 1 - S_L$, and that $S_L = (F_L \cdot L)/F$, expression (3) becomes

$$R = (1 - S_L)\frac{\left(\frac{\partial F_C}{\partial t}\right)}{F_C} + S_L\frac{\left(\frac{\partial F_L}{\partial t}\right)}{F_L}. \tag{4}$$

Rate of change of labor's relative share.—It can be shown (see Appendix B) that the rate of change in the relative share of labor is given by expression (5):

$$\frac{\dot{S}_L}{S_L} = -(1 - S_L)\left[B + \left(\frac{\sigma - 1}{\sigma}\right)\left(\frac{\dot{k}}{k}\right)\right] \tag{5}$$

where the dots indicate total time derivative, σ = elasticity of substitution, and k = capital-labor ratio.

Equation (5) shows that the rate of change of the relative share of labor depends on the bias (B) of technological progress, on the size of the elasticity of substitution (σ), and on the direction of change the capital-labor ratio (k). Of course, if technological progress is neutral, that is, $B=0$, then $\dot{S}_L/S_L$ depends on σ and $\dot{k}/k$. There are many ways that can result in a decline of the relative share of labor. For example, if $\sigma=1$, the relative share will decline only if technological progress is capital-using ($B>0$). The relative share of labor will also decline if $B>0$, $\sigma<1$, and $\dot{k}/k>0$; but the values of these elements are such that $B+(\sigma-1/\sigma)\ \dot{k}/k$ is positive. Expression (5) will be discussed again in terms of demand and supply of labor in the light of the statistical results.

Factor-augmenting technological progress.—Technological change of the factor-augmenting type has been introduced in a CES production function containing factor productivity variables that are functions of time [4]. Assuming constant returns to scale,[4] the factor-augmenting production function may be written as

$$Y = [[\alpha(t)C]^{-\rho} + [\beta(t)L]^{-\rho}]^{-1/\rho} \tag{8}$$

where $\alpha(t)$ and $\beta(t)$ are productivity variables of capital and labor as functions of time, and $\rho=(1-\sigma)/\sigma$. With this production function the bias of technological progress can be expressed in terms of α, β, and σ by using (8) and (2). The bias can be written as

$$B = \left(\frac{\sigma - 1}{\sigma}\right)\left(\frac{\dot{\alpha}}{\alpha} - \frac{\dot{\beta}}{\beta}\right). \tag{9}$$

Substituting (9) into (5), the rate of change of the relative share of labor can be written as

$$\frac{S_L}{S_L} = -(1 - S_L) \cdot \left[\left(\frac{\sigma - 1}{\sigma}\right)\left(\frac{\dot{k}}{k} + \frac{\dot{\alpha}}{\alpha} - \frac{\beta}{\beta}\right)\right]. \tag{10}$$

From equation (10) it appears that the behavior of the relative share of labor, for a given value of σ, depends not just on the capital-labor ratio but also on the changes in the productivity of the two factors. For example, assume that $\sigma>1$. The relative share of labor will increase if the rates of change of the capital-labor ratio and of capital productivity together exceed the rate of change of labor productivity. The term $\dot{k}/k+\dot{\alpha}/\alpha-\dot{\beta}/\beta$ may be viewed as the adjusted capital-labor ratio, that is, physical units of capital and labor adjusted for their productivity [9, p. 313].

Type of factor augmentation.—The form of factor augmentation needs to be specified when statistical estimation is attempted. A common specification is to assume that factor augmentation occurs at a constant exponential rate. Thus $\alpha(t)$ and $\beta(t)$ can be written as

$$\alpha(t) = \alpha_0 e^{\lambda_C t} \text{ and } \beta(t) = \beta_0 e^{\lambda_L t}, \quad \lambda_L, \lambda_C > 0.$$

[4] This assumption is not very restrictive for our purposes. We could have assumed a homogeneous production of degree m, which is written as

$$Y = [(\alpha(t)C)^{-\rho} + (\beta(t)L)^{-\rho}]^{-\frac{m}{\rho}}.$$

The marginal product of labor of this function is

$$\frac{\partial Y}{\partial L} = Y^{1+\rho/m} m(\beta(t))^{-\rho} L^{-\rho-1}$$

and, similarly, the marginal product of capital is

$$\frac{\partial Y}{\partial C} = Y^{1+\rho/m} m(\alpha(t))^{-\rho} C^{-\rho-1}.$$

Taking the ratio of the marginal products, the parameter m cancels out. The resulting expression is given later as equation (14). It follows that the elasticity of substitution defined as

$$\sigma = \frac{d\left(\frac{C}{L}\right)}{\left(\frac{C}{L}\right)} \div \frac{d\left(\frac{\partial Y}{\partial L} \div \frac{\partial Y}{\partial C}\right)}{\frac{\partial Y}{\partial L} \div \frac{\partial Y}{\partial C}}$$

is not affected by the degree of homogeneity of the production function.

Differentiating $\alpha(t)$ and $\beta(t)$ with respect to time and dividing by α and β, we obtain

$$\frac{\dot{\alpha}}{\alpha} = \lambda_C \quad \text{and} \quad \frac{\dot{\beta}}{\beta} = \lambda_L,$$

that is, factor augmentation occurs at a constant rate for both factors of production.

In this paper we have specified $\alpha(t)$ and $\beta(t)$ as

$$(11) \quad \alpha(t) = \alpha_0 t^{\gamma_C}, \quad \beta(t) = \beta_0 t^{\gamma_L} \quad \gamma_C, \gamma_L > 0$$

This formulation implies that

$$\frac{\dot{\alpha}}{\alpha} = \gamma_C t^{-1} \quad \text{and} \quad \frac{\dot{\beta}}{\beta} = \gamma_L t^{-1},$$

that is, the rate of factor augmentation is declining. The rate of change of the relative share of labor can now be expressed as

$$(12) \quad \frac{\dot{S}_L}{S_L} = -(1 - S_L)\left(\frac{\sigma - 1}{\sigma}\right) \cdot \left[\frac{\dot{k}}{k} - (\gamma_L - \gamma_C)t^{-1}\right].$$

Since $0 < S_L < 1$ and $t > 0$, the direction of $\dot{S}_L/S_L$ depends on σ, $\dot{k}/k$, and $(\gamma_L - \gamma_C)$. Our purpose now is to obtain estimates of σ, $\dot{k}/k$, and $(\gamma_L - \gamma_C)$; and this will enable us to explain the declining relative share of labor for American agriculture.

Statistical considerations

Estimation of σ and $\gamma_L - \gamma_C$.—In order to estimate σ and $(\gamma_L - \gamma_C)$ we substitute equation (11) into (8) and obtain

$$(13) \quad Y = \left[(\alpha_0 t^{\gamma_C} C)^{-\rho} + (\beta_0 t^{\gamma_L} L)^{-\rho}\right]^{-1/\rho}.$$

By differentiating (13) with respect to C and L and taking the ratio of the resulting marginal products, we have

$$(14) \quad \frac{F_L}{F_C} = \left(\frac{\beta_0}{\alpha_0} t^{\gamma_L - \gamma_C}\right)^{-\rho}\left(\frac{C}{L}\right)^{1+\rho}.$$

Substituting[5] W/r for F_L/F_C and solving (14) for C/L, we have

$$(15) \quad \frac{C}{L} = \left(\frac{W}{r}\right)^{\sigma}\left(\frac{\beta_0}{\alpha_0} t^{\gamma_L - \gamma_C}\right)^{1-\sigma}$$

since $\sigma = 1/(1+\rho)$ and therefore $\rho/(\rho+1) = 1 - \sigma$. Taking logarithms of (15), we obtain

$$(16) \quad \log\left(\frac{C}{L}\right) = (1 - \sigma)\log\left(\frac{\beta_0}{\alpha_0}\right) + \sigma \log\left(\frac{W}{r}\right) + (\gamma_L - \gamma_C)(1 - \sigma)\log t$$

which can be estimated and supply estimates of σ and $(\gamma_L - \gamma_C)$.

From equation (16) we can estimate only the difference $(\gamma_L - \gamma_C)$, not the individual γ's. There is, however, an alternative approach that provides estimates of σ and γ_L [4, p. 367]. For equation (13) the marginal product of labor is given by

$$(17) \quad \frac{\partial Y}{\partial L} = \left(\frac{Y}{L}\right)^{1+\rho}(\beta_0 t^{\gamma_L})^{-\rho}.$$

Dividing both sides of (17) by W $(W = \partial Y/\partial L)$ and manipulating the resulting expression, we obtain

$$S_L = W^{1-\sigma}(\beta_0 t^{\gamma_L})^{\sigma-1}; \text{ and in logarithms}$$

$$(18) \quad \log S_L = (\sigma - 1)\log \beta_0 + (1 - \sigma)\log W + \gamma_L(\sigma - 1)\log t.$$

Notice that from (18) estimates of σ and γ_L can be obtained without using data on capital and interest rate.

Estimation of $\dot{k}/k$.—The rate of growth of the capital-labor ratio can be estimated directly from the available data on capital stock and labor force. Then the mean value of the estimated $\dot{k}/k$ can be used jointly with the estimates of σ and $(\gamma_L - \gamma_C)$ to explain the changes in the relative share of labor. Alternatively, one can regress $\dot{k}/k$ on time and use the predicted value of $\dot{k}/k$ for the mean year as an estimate of $\dot{k}/k$.

---

[5] This substitution implies that the labor market was in equilibrium and therefore that labor is paid its marginal product. This assumption is not totally satisfactory, but it is the best we can do. The effect of deviations from this assumption on the estimate of the relative share of labor depends on the dynamics of the adjustment process when $F_L \neq W$. The specification of such process is not within the range of our intentions. Generally speaking, however, if wage rates lag behind the level of marginal product the estimated relative share of labor underestimates the true contribution of labor to total production. The opposite holds if wage rates are ahead of the level of marginal product of labor. It should be noted that we are interested in the *changes* in the relative share of labor, and therefore the consequences of the deviations from equilibrium may not disturb our results if the direction and amount of $W - F_L$ remain approximately the same throughout the period we are covering.

Empirical results

Data.—To estimate equations (16) and (18) we need data on total agricultural output (Y), capital services (C), labor employment (L), return to capital (r), and wage rate (W). Estimates of Y, L, and W for the 1949–1968 period are available in the sources referred to earlier. From these data we were able to compute the relative share of labor as shown earlier. The measure of capital used here is based on data reported in [20]. Capital consists of the following items: feed, livestock, seed, fertilizer, repairs and operation of capital items, depreciation and other consumption of farm capital, and interest on farm mortgage debt. The resulting series was deflated by the index of prices paid by farmers (1957–59 = 100). As interest rate we used the Production Credit Association's average cost of loans, which is also reported in [20]. The limited reliability of this cost as an estimate of the return to capital is one reason for using equation (18) to obtain an estimate of the elasticity of substitution. The rate of interest was also deflated by the index of prices paid by farmers.

Estimates of σ, $\gamma_L - \gamma_C$, and γ_L.—For statistical estimation of (16) and (18) an error term needs to be added. Thus we rewrite (16) as

$$\text{(16a)} \quad \log\left(\frac{C}{L}\right)_t = a_0 + a_1 \log\left(\frac{W}{r}\right)_t + a_2 \log t + U_t$$

where

$$a_0 = (1 - \sigma)\log\left(\frac{\beta_0}{\alpha_0}\right),$$

$$a_1 = \sigma,$$

$$a_2 = (\gamma_L - \gamma_C)(1 - \sigma), \quad \text{and}$$

$$U_t \sim NID(0, \sigma_U^2).$$

The assumed distribution of U_t implies that we have multiplied equation (15) by e^u which has a lognormal distribution. Equation (18) can be written as

$$\text{(18a)} \quad \log S_{Lt} = b_0 + b_1 \log W_t + b_2 \log t + V_t$$

where

$$b_0 = (\sigma - 1) \log \beta_0,$$

$$b_1 = 1 - \sigma,$$

$$b_2 = \gamma_L(\sigma - 1), \quad \text{and}$$

$$V_t \sim NID(0, \sigma_V^2).$$

Application of direct least squares to equation (16a) resulted in the following regression equation:

$$\text{(16b)} \quad \log\left(\frac{C}{L}\right) = \underset{(4.92)}{3.011} + \underset{(5.72)}{1.524} \log\left(\frac{W}{r}\right) + \underset{(3.83)}{.197} \log t.$$

$$\text{d.f.} = 17 \quad \bar{R}^2 = .95 \quad \text{D-W} = 1.03$$

The t values are reported in the parentheses. From regression (16b) we obtain

$$\hat{\sigma} = 1.524$$

$$(\widehat{\gamma_L - \gamma_C}) = \frac{a_2}{1 - \hat{\sigma}} = -.375$$

$$\hat{S}_\sigma = .26$$

$$\hat{S}_{(\widehat{\gamma_L - \gamma_C})} = .28^{6}$$

Application of direct least squares to equation (18a) gives the following regression:

$$\text{(18b)} \quad \log S_L = \underset{(-8.16)}{-1.09} - \underset{(-4.07)}{1.44} \log W - \underset{(-2.56)}{1.32} \log t.$$

$$\text{d.f.} = 17 \quad \bar{R}^2 = .91 \quad \text{D-W} = .42$$

Estimates of σ and γ_L derived from regression (18b) are

$$\hat{\sigma} = 2.44 \qquad \hat{S}\hat{\sigma} = .35$$

$$\hat{\gamma}_L = -.916 \qquad \hat{S}\hat{\gamma}_L = .25$$

Our interest is not in the regression coefficients but in the structural parameters σ and $(\gamma_L - \gamma_C)$. From equation (16b) we obtain an

[6] The variance of $(\widehat{\gamma_L - \gamma_C})$ has been estimated by a Taylor's expansion using only the first order terms. Since $(\widehat{\gamma_L - \gamma_C}) = a_2/(1 - \hat{a}_1)$, the variance of $(\widehat{\gamma_L - \gamma_C})$ is

$$V(\widehat{\gamma_L - \gamma_C}) = \left(\frac{1}{1 - \hat{a}_1}\right)^2 V(\hat{a}_2) + \left[\frac{\hat{a}_2}{(1 - \hat{a}_1)^2}\right]^2 V(\hat{a}_1) + 2\left(\frac{1}{1 - \hat{a}_1}\right)\left[\frac{\hat{a}_2}{(1 - \hat{a})^2}\right] \text{Cov}\ (\hat{a}_1, \hat{a}_2).$$

A similar formula has been used for the estimation of variance of other ratios.

elasticity of substitution greater than one and an estimate of $(\gamma_L - \gamma_C)$ that indicates that the productivity of capital in the agricultural sector has increased faster than the productivity of labor. From equation (18b) we obtain an elasticity of substitution greater than two and an estimate of γ_L that is less than zero. Since for the model the value of γ_L has been restricted to positive numbers (see equation (11)), this result is inadmissible. Regression (18b) also suffers from autocorrelation as indicated by the value of the Durbin-Watson statistic. The explanatory power of (16b) is also greater, as the adjusted $\bar{R}^2$ is greater than that of regression (18b). Equation (16b) is therefore preferable to (18b), and the results of (18b) will not be used further. However, an attempt to correct regression (18b) for autocorrelation was made and the results are reported in the next section.

Considering equation (16b), the estimate of σ is directly obtained from the regression coefficient, and its significance can be tested using a t-distribution. The estimated σ is significant at .01 level of significance. The estimate of $(\gamma_L - \gamma_C)$ is obtained indirectly as the ratio of two coefficients. A test of significance for $(\gamma_L - \gamma_C)$ presents a difficulty as the two coefficients forming the ratio, i.e., $a_2/(1-a_1)$, are both normally distributed with nonzero means and different variances. The difficulty is that the distribution of the ratio of two normal variables with nonzero means is unknown.[7] Since the estimate of $(\gamma_L - \gamma_C)$ is greater in absolute value than its standard error $(|1-.3751| > .28)$, we accept it as significant.

Additional estimates of σ, $(\gamma_L - \gamma_C)$, and γ_L.—Additional estimates of σ and $(\gamma_L - \gamma_C)$ were obtained by introducing a Nerlove-type adjustment process in the capital-labor ratio. Since the model is written in logarithms, the adjustment process is expressed as

$$\log\left(\frac{C}{L}\right)_t - \log\left(\frac{C}{L}\right)_{t-1} = \lambda\left[\log\left(\frac{C}{L}\right)_t^* - \log\left(\frac{C}{L}\right)_{t-1}\right] \tag{19}$$

where $(C/L)_t^*$ is the desired capital-labor ratio in period t. Under this formulation the left-hand term of equation (16a) is the desired capital-labor ratio; therefore, by combining (16a) and (19) we obtain the well-known result in equation (20):

$$\log\left(\frac{C}{L}\right)_t = c_0 + c_1 \log\left(\frac{C}{L}\right)_{t-1} + c_2 \log\left(\frac{W}{r}\right)_t + c_3 \log t + U_t \tag{20}$$

where

$$c_0 = \lambda(1-\sigma)\log\left(\frac{\beta_0}{\alpha_0}\right),$$

$$c_1 = 1 - \lambda,$$

$$c_2 = \lambda\sigma,$$

and

$$c_3 = \lambda(\gamma_L - \gamma_C)(1-\sigma).$$

Equation (20) was estimated by a two-stage least squares procedure [12, p. 41] by substituting $\log\ (\hat{C}/L)_{t-1}$ for $\log\ (C/L)_{t-1}$, where $(\hat{C}/L)_{t-1}$ is the predicted value of $(C/L)_{t-1}$ based on the other independent variables. The resulting regression is

$$\log\left(\frac{C}{L}\right)_t = \underset{(2.62)}{2.08} + \underset{(.72)}{.225} \log\left(\frac{C}{L}\right)_{t-1} + \underset{(2.76)}{1.09} \log\left(\frac{W}{r}\right) + \underset{(1.49)}{.193} \log t. \tag{21}$$

$$\text{d.f.} = 15 \qquad \bar{R}^2 = .95$$

From regression (21) we have

$$\hat{\lambda} = .775 \qquad \hat{S}_{\hat{\lambda}} = .72$$

$$\hat{\sigma} = 1.277 \qquad \hat{S}_{\hat{\sigma}} = .42$$

$$\widehat{(\gamma_L - \gamma_C)} = -.88 \qquad \hat{S}_{\widehat{(\gamma_L-\gamma_C)}} = .58$$

These results confirm that the productivity of capital has increased more than the productivity of labor. In terms of a typical statistical test, the hypothesis that σ is equal to unity is accepted at .05 significance level. It may be noted, however, that the estimated value of σ and its standard error give a probability of about 74 percent that σ is greater than unity, using the normal approximation.

[7] If the means of the two variables were zero, the ratio would follow a Cauchy-distribution that has no moments, and thus testing would be impossible.

In an attempt to obtain better estimates of σ and particularly of γ_L from equation (18a), the following iterative procedure suggested by Johnston [13, p. 194] was used.

Step 1. Regress the independent variable $\log S_L$ on the dependent variables $\log W$ and $\log t$ and obtain estimates of the parameters denoted b_0^1, b_1^1, and b_2^1.

Step 2. From the regression in step 1 obtain estimates of the error term V_t^1, and regress V_t^1 on V^1_{t-1} to obtain an estimate of the correlation coefficient ρ denoted ρ_1.

Step 3. Using ρ_1 compute the transformed variables $(\log S_{L,t}-\rho_1 \log S_{L,t-1})$, $(\log W_t - \rho_1 \log W_{t-1})$ and $(\log t-\rho_1 \log t-1)$.

Step 4. Regress $(\log S_{L,t}-\rho_1 \log S_{L,t-1})$, $(\log W_t-\rho_1 \log W_{t-1})$, and $(\log t-\rho_1 \log (t-1))$ to obtain new estimates of the parameters denoted by b_0^2, b_1^2, and b_2^2.

Step 5. Repeat step 2 with the regression results of step 4 and continue the iterations until the residuals are not significantly autocorrelated.

This procedure assumes that the error term of equation (18a) has the following autoregressive structure:

$$V_t = \rho V_{t-1} + Z_t \quad \text{where} \quad Z \sim NID(0, \sigma^2_Z)$$

After two iterations this procedure has given the following results:

$$\begin{array}{lll} b_0 = -.0035 & (t=-.083) & \bar{R}^2 = .77 \\ b_1 = -.6020 & (t=-2.010) & \text{d.f.} = 17 \\ b_2 = -.5030 & (t=-7.210) & \text{D-W} = .92 \\ \rho = .5400 & (t=2.590) & \end{array}$$

From these estimates we have

$$\hat{\sigma} = 1.602 \qquad \hat{S}_{\hat{\sigma}} = .30$$
$$\hat{\gamma}_L = -.835 \qquad \hat{S}_{\hat{\gamma}_L} = .46$$

Notice that the estimate of the elasticity of substitution is now consistent with the other two estimates obtained from equations (16a) and (18a). It is also statistically greater than unity. The estimate of γ_L retains its negative sign, but now it is insignificant at the .05 level of significance. Although the estimate of γ_L is unsatisfactory, these results suggest that the elasticity of substitution is most likely greater than one.[8,9]

Estimates of $\dot{k}/k$ and $\dot{S}_L/S_L$—Two estimates were obtained for each rate of growth. The first estimate is simply the mean value of all observations; that is, the estimate is based on the observable quantities of capital and labor for $\dot{k}/k$, and employment, wage rate, and total product for $\dot{S}_L/S_L$. The estimates are

$$\text{(a)} \quad \begin{array}{ll} \dfrac{\dot{k}}{k} = .0626 & \text{standard error of } \dfrac{\dot{k}}{k} = .019 \\ \dfrac{\dot{S}_L}{S_L} = -.0428 & \text{standard error of } \dfrac{\dot{S}_L}{S_L} = .0264 \end{array}$$

The second estimate was obtained by regressing each rate of growth on t and t^2 (t=time) and estimating the theoretical value of the rate of growth for the mid-value of t. Thus we received

$$\text{(b)} \quad \begin{array}{ll} \dfrac{\dot{k}}{k} = .06703 & \text{standard error of } \dfrac{\dot{k}}{k} = .067 \\ \dfrac{\dot{S}_L}{S_L} = -.053 & \text{standard error of } \dfrac{\dot{S}_L}{S_L} = .047 \end{array}$$

---

8 Quirino Paris has suggested that an independent estimate of the elasticity of substitution can be obtained by using the following expression provided by Allen [1, p. 373]:

$$(1') \qquad e_L = -[(1 - S_L)\sigma + S_L e_Y]$$

where e_L=price elasticity of demand for labor, S_L=relative share of labor, σ=elasticity of substitution, and e_Y=price elasticity of demand for output defined as $e_Y = -(P/Y)\cdot(dY/dP)$.

Estimates of e_L are available in Wallace and Hoover [22] and Bauer [2]. The estimates are respectively -1.433 and -1.482. The price elasticity of demand for agricultural commodities may be assumed to be approximately $-.5$. For example, Brandow [3] has found the elasticity of demand for nuts and fruits to be $-.35$, and George [11] has estimated the elasticity of demand for fresh fruits and canned fruits and vegetables to be equal to $-.6$ and $-.4$ respectively. The average relative share of labor has been estimated in this paper to be equal to .294. Thus $1-S_L=.706$ Using $e_L=-1.482$ and $e_Y=.35$, the elasticity of substitution is estimated from equation (1′) above to be equal to 1.95. Using $e_L=-1.433$ and $e_Y=.5$ the elasticity of substitution is 1.82; and for $e_Y=1.0$, $\hat{\sigma}=1.61$.

If one uses Ruttan and Stout's [18] mean estimates for the relative share of labor for the period 1947–1957, where $S_L=.267$, with $e_L=-1.433$ and $e_Y=.5$, the elasticity of substitution becomes 1.77.

In view of the result obtained from equation (21) where, formally speaking, the elasticity of substitution was found to be no different from unity, these additional results are helpful and clearly support the findings that $\sigma>1$. It seems clear to us that the elasticity of substitution is greater than unity.

9 An additional source of confidence in the estimates of the elasticity of substitution is the work done by Kaneda [14]. He has found $\hat{\sigma}=1.1368$ with S.E. = .0236 and thus $\hat{\sigma}$ is greater than unity. Our estimates tend to be higher, but the difference may be explained by the longer time-period data available to us. In the context of this study Kaneda's footnote 4 [14, p. 205] is particularly relevant.

It appears that the estimates of $\dot{k}/k$ are close together, but the estimate in (a) is preferable because of its small standard error. The estimates of $\dot{S}_L/S_L$ differ substantially; and again using the reliability of the estimate as a criterion, we choose estimate (a) as preferable. Thus in the subsequent analysis we use $\dot{k}/k = .0626$ and $\dot{S}_L/S_L = -.0428$ as estimates of the two rates of growth. For completeness, we also use the other two values of $\dot{S}_L/S_L$ presented in Table 1 in combination with the same value of $\dot{k}/k$.

Sources of decline in the relative share of labor

Equipped with the information obtained from the estimation of the basic equation (16), we can now look for the sources of decline in the relative share of labor in American agriculture from an empirical point of view. For convenience we reproduce the basic relationship expressed in equation (12):

$$\frac{\dot{S}_L}{S_L} = -(1 - S_L)\left(\frac{\sigma - 1}{\sigma}\right) \cdot \left[\frac{\dot{k}}{k} - (\gamma_L - \gamma_C)t^{-1}\right]. \tag{12}$$

Now we estimate $\dot{S}_L/S_L$ from equation (12) based on the estimates of σ, $(\gamma_L - \gamma_C)$, $\dot{k}/k$, and the three estimates of the mean of the relative share of labor presented in Table 1. Three estimates of $\dot{S}_L/S_L$ were obtained, based on

$$S_L = .294 \qquad S_L' = .501$$

and

$$S_L'' = .282$$

each combined with

$$\hat{\sigma} = 1.524, \qquad (\widehat{\gamma_L - \gamma_C}) = -.375$$

and

$$\frac{\dot{k}}{k} = .0626.$$

The obtained estimates are

(i) $\dot{S}_L/S_L = -.0243,$ based on $S_L = .294$

(ii) $\dot{S}_L/S_L = -.0172,$ based on $S_L' = .501,$

and

(iii) $\dot{S}_L/S_L = -.0247,$ based on $S_L'' = .282.$

Observe now that the three estimates of $\dot{S}_L/S_L$ just obtained fall within the corresponding 5 percent confidence limits that can be constructed from the direct estimates of $\dot{S}_L/S_L$ presented in Table 1. This increases our degree of confidence in the estimates of σ and $(\gamma_L - \gamma_C)$. Of course, the various estimates differ from each other. The important point, however, is that the elasticity of substitution is greater than unity, and the difference of the productivity parameters is consistently negative. Let us now combine these two findings.

Technological progress in American agriculture has been capital-using. This can be seen by means of equation (9). From the results of equation (16a), for example, we have:

$$B = \frac{\sigma - 1}{\sigma}(\gamma_C - \gamma_L)t^{-1} = (.344)(.0375)$$
$$= .129 > 0.$$

According to the definition of bias used here, this means that technological progress has increased the marginal product of capital relative to that of labor. Given a factor-price ratio, this would give an incentive to producers to substitute capital for labor, that is, to increase the capital-labor ratio. In fact, the capital-labor ratio in physical units has gone up. Also, the adjusted capital-labor ratio, the expression in the brackets in equation (12), has gone up. As it is shown in equation (12), the change in the relative share of labor depends not only on the changes in the capital-labor ratio but also on the elasticity of substitution which has been found to be greater than unity. These two factors combined result in a decline in the relative share of labor, as it can be seen from equation (12).

Within the framework of the agricultural labor market, the decline in the relative share of labor can be explained as follows. Given the volume of total output, the factor-price ratio, and the easiness of capital-labor substitution ($\sigma > 1$), capital-using technological progress will reduce the demand for labor. With no changes in the supply of labor, the result would be a decline in wages and employment and therefore a decline in the relative share of labor and a corresponding increase in the relative share of capital. Of course, the volume of total output has increased in the period covered in this study, and the supply schedule of labor was

shifted to the left with the continuing movement of labor from the agricultural to the nonagricultural sector. These two changes (increased output and rural-urban migration) have been strong enough to increase the wage rate in the agricultural labor market, but the increase in output has not been strong enough to outweigh the effect of labor-saving technological progress and to prevent a decline in farm employment. The data show that the wage bill (W·L) has decreased and output has increased. Thus the relative share of labor (WL/Y) has declined.

Elasticity of substitution, technological progress, and labor's relative share in the farm and nonfarm sectors: a comparison

It is interesting to compare our results for agriculture with some similar results obtained for the nonagricultural sector for approximately the same period of time. Ferguson [7] and McKinnon [17] have found that for most industries the elasticity of substitution is less than unity. Ferguson and Moroney [9] have found that it is substantially less than unity. In our study the elasticity of substitution is found to be substantially greater than unity.

The bias of technological progress varies from industry to industry. Ferguson and Ferguson and Moroney in the same studies have found that both capital-using and labor-using technological changes have occurred in the postwar period. However, it appears that a capital-using technology is introduced more often than a labor-using one. In agriculture technological progress has been capital-using.

In all industries except three (one, tobacco, with a decline and two with no change) the relative share of labor has increased [9]. The average rate of increase for all industries is approximately .009. In agriculture the relative share of labor has decreased with an average rate of −.0391.

It is not within the scope of this study to compare the increasing share of labor in manufacturing with the decreasing share of labor in agriculture. We suggest, however, that the difference in the direction of changes may be partly explained by the differential rate of growth of output in the two sectors and the different degree of labor mobility in the two labor markets, given of course the differences in the nature of production that leads to different elasticities of substitution and the rate of technological advancement.

Summary and Concluding Remarks

In the postwar period the relative share of labor in U. S. agriculture has decreased approximately 50 percent, from 42.71 percent in 1949 to 19.99 percent in 1968. This decline is in contrast to the postwar development in manufacturing where the relative share of labor has increased.

Within the framework of neoclassical theory of production and distribution we have attempted to explain the decline in labor's relative share by estimating the elasticity of substitution, the changes in the capital-labor ratio, and the difference in the factor productivity indices. The estimation is based on a constant elasticity of substitution production function which assumes factor-augmenting technological change and constant returns to scale. The rate of factor augmentation is assumed to be declining. The derived statistical models provide us with estimates of the bias of technological change, the elasticity of substitution, and the difference of the factor-augmentation parameters.

The obtained estimates show that (1) according to Hicks' definition of neutrality of technological progress, American agriculture is characterized by capital-using technological progress; (2) the elasticity of substitution is greater than unity; and (3) productivity of capital in agriculture increases faster than productivity of labor. The capital-labor ratio is increasing, and when adjusted for factor-productivity changes it increases even faster.

This analysis refers to the demand side of the labor market and it suggests that the demand for labor is declining. For the explanation of the declining share of labor, the supply side of the labor market needs to be considered. It is well-known that supply of labor in agriculture is also declining, primarily as a response to the relatively increasing economic opportunities in the urban areas. These changes suggest that the product $W \cdot L$, which is the wage bill and the numerator of the definitional formula of relative share of labor ($S_L = WL/Y$), may increase, decrease, or remain constant. Actually it has decreased from approximately $12.8 billion in 1949 to $8.3 billion in 1968. Therefore, although output has increased only moderately, the relative share of labor has decreased substantially.

In view of the fact that Cobb-Douglas production functions (with elasticity of substitu-

tion equal to one) have been traditionally used in agriculture, our finding that the elasticity of substitution appears to be greater than unity has special significance for further research. We suggest that the assumption of unitary elasticity of substitution may not be appropriate, and we may have to sacrifice the simplicity of the Cobb-Douglas production function and adopt a CES production function. Also, our finding that the productivity of capital has increased more than the productivity of labor should make the reader cautious as to the meaning of productivity indices, such as productivity per man-hour.

The reader would have noticed that we have not discussed the causes of factor-augmentation This is a topic in the area of investigations of the sources of productivity growth and falls outside the scope of this study. As far as labor is concerned, however, one may mention the increasing volume of current research that attributes increases in labor productivity to the improving quality of labor input due primarily to the educational attainments of the labor force.

Admittedly, this study is just a first cut into a complex problem with important social consequences. An obvious next step is to examine the changes in the relative share of labor at the regional level. Any observed differences among regions would then raise the question of the effect of regional differences in the rate of industrial development on the agricultural labor market, and useful policy suggestions may be derived. Further, our study lends support to the thesis that outmigration from agriculture has not been fast enough, and thus it suggests that more attention should be given to the supply of labor side of the market with emphasis on the causes of labor immobility.

Appendix A. Basic time series used in the study

Year	$W\cdot L$ (million constant dollars)	W/r	C/L	$\dot{k}/k$	S_L	$\Delta S_L/S_L$	S_L'	$\Delta S_L'/S_L'$	S_L''	$\Delta S_L''/S_L''$

Appendix B

We want to show that

$$(5)\quad \frac{\dot{S}_L}{S_L} = -(1-S_L)\left[B + \left(\frac{\sigma-1}{\sigma}\right)\left(\frac{\dot{k}}{k}\right)\right].$$

It is shown [8, pp. 224–227] that the rate of the marginal product of labor can be written as

$$(6a)\quad \frac{\dot{F}_L}{F_L} = R - (1-S_L)B + \frac{(1-S_L)}{\sigma}\left(\frac{\dot{k}}{k}\right)$$

and the rate of growth of output can be written as

$$(6b)\quad \frac{\dot{F}}{F} = R + (1-S_L)\frac{\dot{k}}{k} + \frac{\dot{L}}{L}.$$

From the definition of the relative share of labor, i.e., $S_L = WL/Y$, by taking total time derivative of S and dividing both sides by S we obtain

$$(7)\quad \frac{\dot{S}_L}{S_L} = \frac{\dot{W}}{W} + \frac{\dot{L}}{L} - \frac{\dot{Y}}{Y}.$$

Remembering the assumption that $W = F_L$ and substituting (6a) and (6b) into equation (7), equation (5) is obtained.

Tariffs, Nontariff Distortions, and Effective Protection in U. S. Agriculture*

LARRY J. WIPF

This paper extends the effective-protection concept to include tariff and nontariff trade distortions and also the entire structure of domestic farm policy measures. Nominal and effective rates of protection are then presented for disaggregated agricultural production and processing industries for the years 1958, 1963, and 1968. The estimates reveal that nontariff measures give rise to extremely high effective protection rates in certain agricultural sectors; in others, tariff and nontariff measures affecting intermediate inputs have important taxation effects. The analysis also indicates that agricultural policy changes have substantially altered the rates of protection accorded certain agricultural sectors.

IN RECENT YEARS the concept of effective tariff protection has received considerable attention by international trade specialists. This concept of protection is concerned with the production side of the economy and arises from the fact that the existence of intermediate goods complicates the effects upon industry levels of operations of the structure of nominal rates. In particular, recent contributions have recognized that

> . . . a tariff on a good used in a productive process is equivalent to a tax on the output of that process, and the consequent necessity of distinguishing sharply between the structure of tariff rates on commodities entering international trade (*nominal rates*), and the structure of rates of protection accorded by the tariff structure to the specific processes or stages of production that make up the productive system (*effective rates*) [4, p. 10].[1]

The effective-rate-of-protection concept has moved rapidly from theory to measurement of effective tariff levels for the manufacturing sectors of various countries.[2] On the other hand, presumably because of the complexities of agricultural policies and the resulting stringent data requirements, the agricultural sectors have usually been omitted from the analysis. Nevertheless, the application of the effective-protection concept need not be limited to the analysis of tariff protection. In this paper it is extended to include (1) other trade-distorting measures such as quantitative restrictions, variable levies, and export subsidies; and (2) indirect taxes, domestic price support provisions, and subsidies—such as direct income payments and cost-lowering production aids—which directly affect only domestic producers. Nominal and effective protection estimates are then presented for disaggregated U. S. agricultural production and processing sectors involving the years 1958, 1963, and 1968. In addition, variations in these rates of protection are related to agricultural policy changes over the period 1958–1968.

The Effective Protection Model

We begin by considering the effective-protection concept. The effective rate of protection afforded a particular domestic industry depends not only on the tariff and nontariff policies affecting its final output but in addition is a function of the input coefficients of this sector and the tariff and nontariff distortions affecting the inputs used by this industry. More explicitly, the effective rate of protection of industry j (g_j) is defined as the percentage difference between the industry's value added per dollar of output under protection (v_j') and its value added per dollar of output in the absence of tariff and nontariff distortions (v_j), as shown in the following equation:

$$g_j = \frac{v_j' - v_j}{v_j} \tag{1}$$

In this model we make the following assumptions:

1. All production functions are of a fixed coefficient form with zero elasticity of substitution between intermediate inputs and primary factors.

* The author wishes to acknowledge the helpful suggestions and criticisms of Robert E. Baldwin, D. Lee Bawden, James E. Anderson, W. G. Waters, and Josef C. Brada. Financial assistance was primarily provided by the Department of Agricultural Economics at the University of Wisconsin.

[1] Italics mine.

[2] For a partial survey of the literature see Balassa [1], Basevi [2], Corden [3], and Johnson [4].

LARRY J. WIPF *is assistant professor of economics at The Ohio State University.*

2. All goods are traded before and after the introduction of protection.

3. Supplies of imports are infinitely elastic.

4. The elasticity of demand for all exports is infinite.

5. Primary factors are mobile nationally but immobile internationally, fixed in terms of total supply for the economy, and available in less than infinitely elastic supply for a particular industry.

Under these assumptions and given input-output data valued at world market prices, free trade and protected value added (per dollar of output) can be written as

$$(2) \quad v_j = 1 - \sum_i a_{ij}$$

$$(3) \quad v_j' = 1 + T_j + s_j - \sum_i a_{ij}(1 + T_i)(1 + e_i)$$

where

a_{ij} = the value of the ith input required per dollar value of output of industry j, at free trade prices;

T_j = total nominal rate for tariff and nontariff measures (except direct subsidy payments) on final output of industry j;

s_j = direct subsidy payment rate received by domestic producers in industry j;

T_i = total nominal rate for tariff and nontariff measures (except indirect taxes) on input i;

e_i = excise tax rate on intermediate input i.

Now substituting equations (2) and (3) into (1), we obtain the following expression for the effective rate of protection:

$$(4) \quad g_j = \frac{T_j + s_j - \sum_i a_{ij}(T_i + e_i + T_i e_i)}{1 - \sum_i a_{ij}}$$

Note that tariffs, import quotas, and price-distorting domestic policies may either subsidize or tax domestic production, depending on whether they apply to an output or an input. In contrast, domestic output subsidies increase protection directly in the industries receiving subsidy payments but do not tax industries that use these commodities as inputs, since the market prices of these goods are not affected by subsidy payments. It should also be mentioned that owing to the existence of border tax adjustments, which impose excise taxes on imports and rebate these taxes on exports, domestic and foreign products carry the same excise tax burden. Thus, a selective indirect tax, such as an excise tax, does not affect effective-protection rates in industries producing the goods on which these taxes are levied. However, the effective rate of protection decreases in those industries that use the taxed products as inputs but are not permitted to receive a rebate for indirect taxes paid on inputs. This being the case, the intermediate input coefficients are also adjusted for the price-raising effects of indirect taxes.

The effective rate formula shown in equation (4) can be rewritten as

$$(5) \quad g_j = (T_j + s_j) + \frac{(T_j + s_j - \bar{d}_i) \sum_i a_{ij}}{1 - \sum_i a_{ij}}$$

where

$$\bar{d}_i = \frac{\sum_i a_{ij}(T_i + e_i + T_i e_i)}{\sum_i a_{ij}}$$

is a weighted average of the tariff and nontariff measures that act to raise the cost of inputs entering the production process of industry j. This last equation makes it easy to identify the critical points in the relationship between nominal and effective rates of protection. In particular, note that

$$g_j > T_j + s_j \qquad \text{when } T_j + s_j > \bar{d}_i$$
$$g_j < T_j + s_j \qquad \text{when } T_j + s_j < \bar{d}_i$$
$$g_j = T_j + s_j \qquad \text{when } T_j + s_j = \bar{d}_i$$

Also note that the effective rate of protection can be negative, implying a tax on domestic production. This occurs when the numerator of equation (4) is less than zero (i.e., when the protective measures on final output are less than the weighted sum of tariff, quota, and domestic price-distorting policies on intermediate inputs). Negative effective rates may exist for import-competing industries and are extremely likely for exportable goods that receive no export assistance. The following analysis reveals the distorted view of protection that can be obtained by looking at selected tariff and nontariff measures in isolation and points out the need to consider the net effects of tariff and nontariff measures upon industry levels of operation.

Up to this point the various effective-protec-

tion formulae have been developed by starting from a free-trade situation and then introducing trade-distorting measures. While this approach is convenient for exposition, the resulting formulae are not suited for empirical application since we do not observe free-trade input-output values. Now, considering an input-output system expressed in terms of actual transaction flows valued at domestic prices, the effective-rate-of-protection formula can be reformulated as:

$$g_j = \frac{\dfrac{X_j'}{(1+e_j)} - \sum_i M_{ij}'}{\dfrac{X_j'}{(1+T_j)(1+e_j)} - \sum_i \dfrac{M_{ij}'}{(1+T_i)(1+e_i)}} - 1 \tag{6}$$

where X_j' is the total domestic value of industry j's output at consumers' prices and M_{ij}' is the total domestic value of the intermediate input i used in the production of j. Equation (6) represents the general type of formula used to compute the various effective protection rates presented in the next section.

Empirical Results

Estimates of nominal and effective rates of protection are reported for two stages of U. S. agricultural production: the farm level and the processed-product level. In the case of effective protection rates, calculations were made for total protection (i.e., combination of tariff and nontariff measures) and for the separate effects of tariff and nontariff distortions. The computations are based on U. S. input-output data for 1958 and information pertaining to trade distortions affecting either intermediate inputs or final output of a given industry in 1958, 1963, and 1968.[3] The distortions considered include import duties, import quotas and controls, the price-increasing provisions of domestic farm programs (together with the import quotas and export subsidies that accompany these measures), direct subsidy or support payments, American selling price valuation practices, federal subsidization of highway transportation, and indirect taxes.

Table 1 presents rates of protection for 17 farm-level sectors, 11 processing industries, and 3 composite groups formed by these sectors for the years 1958 and 1963.[4] Columns (1) and (2) show the total nominal and total effective rates for 1958; effective tariff and effective nontariff rates are listed in columns (3) and (4); and the corresponding rates for 1963 are shown in columns (5) to (8).

First we shall consider the 1958 rates of protection. The difference between the total nominal and total effective rates is considerable. The range of the total effective rates is approximately four times the range of the corresponding nominal rates. Total nominal rates ranged from zero percent for forest products to about 62 percent for sugar processing, while the total effective rates ranged from a minus 28 percent for poultry and eggs to approximately 228 percent for sugar crops. Even more important is the fact that the degree of escalation in the effective rates varies greatly for the individual agricultural sectors. We find that the total effective rates for food grains and sugar crops are almost four times as large as their total nominal rates. In contrast, the total effective rates for sectors such as meat animals and oil-bearing crops differ little from their nominal rates, indicating that the protective measures for final output are approximately offset by cost-increasing measures affecting intermediate inputs used by these sectors. Also note that negative effective rates occur in 6 of the 28 disaggregated agricultural sectors, signifying that instead of being

[3] Because 1958 input–output data were used for all effective rate calculations, the rates for 1963 (1968) should be interpreted as measuring the effective protection levels that would have occurred in 1958 given the adoption of the policies existing in 1963 (1968). These rates would be equal to the actual effective protection levels in 1963 (1968) if the input–output structures were truly identical in 1958 and 1963 (1968). A more detailed discussion of data sources and computational procedures is contained in the appendix to this paper as well as in my dissertation [11].

[4] The three industry groups—livestock and livestock products, other agricultural products, food and kindred products—are identified as sectors 1, 2, and 14, respectively, in the 1958 input–output study [10]. The 17 farm-level sectors correspond to a disaggregation of sectors 1 and 2, while the nine food processing sectors are a disaggregation of industry 14. The two remaining processing sectors—tobacco manufacturers and fabrics, yarn, and thread mills—correspond to sectors 15 and 16 in the 1958 input–output table.

Table 1. Nominal and effective protection in U. S. agriculture: 1958 and 1963[a]

Input-output sector	1958 protection rates				1963 protection rates

[a] The following abbreviations are used: total nominal rate (TOT NOM), total effective rate (TOT EFF), effective tariff rate (EFF TRF), and effective nontariff rate (EFF NT).

protected these sectors are in fact taxed by the structure of tariff and nontariff policies.

A comparison of columns (3) and (4) indicates the relative importance of tariff and nontariff measures for U. S. agriculture in 1958. The effective tariff rates (which should be interpreted as measuring the effective rates of protection that the national tariff structure would provide in the absence of nontariff measures) suggest that tariff protection is significant for a number of the farm-level and processing-level sectors. On the other hand, the effective nontariff rates clearly indicate the protectionistic tendencies of domestic farm programs for the dairy, food grain, cotton, and sugar crop sectors. It is interesting to note the interaction between tariff and nontariff measures for certain sectors. For example, in the case of the confectionery products sector, nontariff measures on inputs deduct 16.3 percentage points from the rate of protection of value added afforded this industry by the tariff structure alone.

The rates of protection for 1963 allow us to analyze the manner in which protection has changed over the period 1958–1963. The feed grain commodities provide an interesting example of how policy changes have altered effective protection rates in agriculture. The policy of setting domestic support prices for feed grains above world market levels was reflected in an effective rate of 22.6 percent for the year 1958. Starting in 1963 the price support loan rates were set at approximately world levels, while both price support and acreage diversion payments were authorized for feed grains. These provisions are more consistent with trade liberalization policies and in 1963 gave rise to an effective rate of only 8.8 percent. The decline in the domestic price-support levels for grains

also affected the rates of protection for the agricultural sectors that use these commodities as inputs. For example, this policy change was the major factor leading to an increase in effective nontariff protection (i.e., lower negative rates) for the meat animal, poultry and egg, and beverage industries. Total effective protection also increased in the meat animal and poultry and egg sectors, while the total effective rate declined for the beverage industry because of a concurrent decrease in tariff duties on beverage imports.

The variations in the rates of protection accorded the sugar sectors between 1958 and 1963 perhaps warrant further explanation. Normally the domestic market price of raw sugar has been maintained above world market levels by assigning quotas to both domestic and foreign producing areas that supply the United States with sugar. This was the case in 1958, when the effective rate of protection accorded to the sugar processing industry exceeded 200 percent. In contrast, in 1963 the world market price of sugar rose sharply, and export controls were used to keep the domestic price of sugar below the world-market level. This resulted in a negative effective protection rate for the sugar processing sector. Similarly, effective protection for sugar crops declined from almost 230 percent in 1958 to about 75 percent in 1963; nevertheless, sugar act payments received by domestic producers of sugar beets and sugar cane prevented the effective protection rate from becoming negative.

Spearman rank correlation coefficients were computed to determine whether the rankings of effective protection rates had changed between 1958 and 1963. The rank correlation coefficient between the 1958 total effective rates shown in column (2) and the corresponding 1963 rates shown in column (6) is .677. The null hypothesis that the two sets of rankings are unrelated was rejected at the .05 level. Thus, even though the effective rates of protection for various sectors have changed between 1958 and 1963, their relative rankings have not been significantly altered.

Rates of protection accorded the farm-level sectors were also estimated for the year 1968. These rates, listed in Table 2, make it possible to analyze the effects of additional farm policy changes on effective protection rates in agriculture. The modifications of the wheat program in the late 1960's had little impact on effective protection afforded the food grain sector, which is dominated by wheat production. In 1968 the national price-support loan rate for wheat was set at approximately competitive world-market levels while producers received direct income payments in the form of domestic marketing certificates. These provisions resulted in an effective rate of protection for food grains of 143 percent for the year 1968. This is only slightly lower than the 1958 rate, when domestic support prices for wheat were set above world-market levels but no marketing certificates were issued.

Table 2. Nominal and effective rates of protection in the U. S. farm production sectors: 1968

Input-output sector	Total nominal (1)	Total effective (2)	Effective tariff (3)	Effective nontariff (4)
Farm-level sectors				
Meat animals	7.5	13.8	13.2	0.6
Poultry and eggs	0.8	−19.6	−16.6	−3.0
Farm dairy products	16.8	48.2	− 3.4	51.6
Other livestock products	2.5	3.3	3.5	−0.2
Food grains	8.4	143.5	− 2.7	146.2
Feed crops	0.4	8.1	0.0	8.1
Cotton	0.3	100.8	− 1.3	102.1
Tobacco	17.0	28.2	24.5	3.7
Oil-bearing crops	11.3	16.4	− 0.8	17.2
Vegetables	12.4	17.9	20.8	−2.9
Fruits	8.4	9.1	11.8	−2.7
Tree nuts	20.1	25.5	35.2	−9.7
Legume and grass seeds	6.9	8.7	11.3	−2.6
Sugar and sirup crops	195.8	662.2	72.2	590.0
Miscellaneous crops	5.8	13.0	15.2	−2.2
Forest products	0.0	− 0.9	− 0.1	−0.8
Greenhouse products	3.7	3.2	4.4	−1.2
Aggregated sectors				
Livestock and livestock products	8.5	18.9	7.5	11.4
Other agricultural products	7.6	32.3	6.0	26.3

Revisions were also made in the U. S. cotton program between 1963 and 1968. By 1968 market support of cotton was lowered to approximately competitive world-price levels while incomes of producers were supplemented by use of direct price-support and acreage diversion payments. These revisions appear to have contributed to a rise in the effective protection level for cotton. The total effective rate for cotton was estimated to be about 100 percent in 1968; the corresponding rates were 57 percent in 1958 and 95 percent in 1963.

It is interesting to note that the effective rates of protection have declined between 1958 and 1968 in the vegetable, fruit, tree nut, and greenhouse and nursery product sectors. Nontariff distortions have generally been unimportant for these sectors.

Spearman correlation coefficients for the farm-level sectors also reveal a significant degree of association between rankings of effective protection rates in different years over the

Table 3. Nominal and effective protection rates in U. S. crop production: 1958, 1963, 1968

Input-output sector	1958		1963		1968	
	Total nominal	Total effective	Total nominal	Total effective	Total nominal	Total effective
Wheat	40.0	139.7	42.3	159.9	8.6	153.0
Rye	43.7	168.3	0.0	−15.8	0.0	−16.5
Rice	44.0	151.7	36.4	120.4	7.3	13.7
Buckwheat	5.3	7.0	3.6	1.0	1.4	− 4.3
Corn	11.4	19.3	0.0	7.6	0.0	20.0
Oats	26.5	67.7	0.0	−16.9	0.0	−15.8
Barley	19.4	40.7	0.0	− 1.4	0.0	−13.2
Sorghum	23.7	43.3	0.0	8.0	0.0	23.5
Soybeans	0.0	−5.1	0.0	− 6.8	0.0	− 6.7
Peanuts	37.3	102.7	71.4	203.3	69.3	204.0
Flaxseed	22.8	47.4	2.2	− 5.7	14.8	26.2
Cotton	19.8	57.1	32.2	95.0	0.3	100.8
Tobacco	11.7	19.0	15.0	24.4	17.0	28.2
Sugar crops	57.4	227.7	−6.3	72.6	195.8	662.2

period 1958–1968. The rank correlation between the 1958 and 1963 total effective rates is .882 while the corresponding coefficients for the 1958–1968 and for the 1963–1968 rankings are .882 and .919, respectively. Further analysis, however, reveals that significant changes have occurred in the pattern of protection for individual commodities within the major crop sectors.

Table 3 presents nominal and effective rates of protection involving 14 crop commodities for the years 1958, 1963, and 1968. Notice the substantial variation in these rates of protection between 1958 and 1968. The Spearman rank correlation coefficient between the 1958 effective rate of protection rankings for these farm crops and the corresponding 1963 rankings is .323; similarly, the rank correlation between the 1958 and 1968 rates is .279. On the other hand, the Spearman coefficient between the 1963 and 1968 rates is substantially higher at .811. In the first two cases the null hypothesis that the rankings are unrelated was accepted at the .05 level of significance. These results are not surprising since major farm policy changes, involving many of these individual crops, have occurred between 1958 and 1968.

Rank correlations were also computed to measure the degree of association between changes in effective protection rates and changes in output for the farm crops shown in Table 3. The Spearman coefficient between the rankings of percentage changes in effective rates over the 1958–1963 period and the corresponding rankings of percentage changes in output is .560. By coincidence the rank correlation between the 1958–1968 effective rate changes and the 1958–1968 output changes is also .560. In both cases the null hypothesis of no relation was rejected at the .05 level.

Summary and Conclusions

This investigation was undertaken in an attempt to help fill a void in the literature pertaining to the levels of protection in agricultural industries of various countries. In particular, the theory of effective tariff protection was extended by introducing nontariff trade distortions and domestic farm policy measures. Then, as an application of this concept of protection, effective protection rates were calculated for disaggregated U. S. agricultural production and processing industries for the years 1958, 1963, and 1968. In the past these sectors have usually been excluded from such analysis.

The rates of protection reported in this paper reveal certain general features: (1) the nominal and effective rates of protection for a particular industry are often considerably different; (2) effective protection rates vary greatly from one agricultural sector to another; and (3) nontariff distortions give rise to extremely high effective protection in certain agricultural sectors, while in others tariff and nontariff measures affecting intermediate inputs have important taxation effects. High effective tariff rates, on the other hand, were notable for several other agricultural sectors. The analysis also indicates that a significant level of correlation exists between rankings of effective protection rates in different years over the period 1958–1968 when all of the agricultural sectors are considered. However, the opposite conclusion was reached when the analysis focused upon individual farm crop sectors involved in agricultural policy changes. Finally, Spearman rank correlation coefficients reveal a substantial degree of association between changes in effective-rate rankings for individual farm crops and the corresponding rankings of actual changes in crop production.

Although the absolute magnitudes of the effective rates of protection in certain U. S. agricultural industries appear to be quite high in some cases, they are likely to be equaled or exceeded by rates of protection in the agricultural sectors of other industrially developed nations. For example, as reported in a recent

UNCTAD study [5], many of the nominal ad valorem equivalents for variable levies which affected agricultural commodities imported by the EEC during 1967 exceeded 50 percent, approaching 300 percent in the extreme case of butter. These nominal rates could lead to extremely high effective rates of protection. In the future it may be desirable to extend this analysis to a comparative study of agricultural protection in a number of the industrially developed nations.

In conclusion, something should be said about the rather rigorous assumptions underlying the empirical analysis of this paper. The use of input-output data imposes a crucial assumption with respect to substitutability of inputs in production. In addition, the assumption regarding the relationship between domestic and foreign prices may well be a poor approximation of reality. Thus the results should be interpreted with a certain degree of caution. Yet it still seems useful to compute effective rates of protection. Unlike the traditionally reported nominal rates of protection, effective protection rates do take into account the effects of tariff and nontariff distortion measures on intermediate inputs as well as on final output. In addition, effective rates of protection must be considered better indicators of resource shifts than nominal rates.

Appendix

Data Sources and Computational Procedures

Input-output data for the 17 primary agricultural sectors were obtained from unpublished background tables prepared by the U. S. Department of Agriculture in conjunction with the 1958 input-output tables published by the Department of Commerce. Additional unpublished data furnished by the USDA were used to further disaggregate many of the input items used by the primary agricultural sectors. These data made it possible to identify many of the individual farm level inputs; in addition, many nonagricultural inputs were identifiable at the four-to-six digit level of the Standard Industrial Classification (SIC) code. The input-output data for the processing industries were taken from additional input-output detail published by the Department of Commerce [9]. Here again, additional information procured from the Department of Agriculture was utilized to further disaggregate the inputs purchased by the processing industries.

The data needed to compute the various nominal rates of protection entering the effective-protection formulae were taken from numerous sources. Information on duties, value of imports, and transportation costs to U. S. ports for individual primary agricultural commodities was supplied by the USDA for the years 1958 and 1963. These data were supplemented with information contained in the U. S. tariff schedules. Data for the 1958 and 1963 tariff rate calculations for the processed products and nonagricultural inputs were published by the Department of Commerce [6, 7]. Information on imports and duties for 1968 was available for individual tariff schedule commodities [8]. A cross classification between SIC and TSUSA (Tariff Schedules of the United States Annotated) numbers was used to obtain a correspondence between these data and the input-output industries. The data on duties collected, foreign port value of imports, and transportation costs to U. S. ports were used to compute nominal tariff rates expressed in terms of c.i.f. value. When data on freight and insurance costs were not available for individual commodity items, the ratio of f.o.b. to c.i.f. import values given for commodity groups in the 1958 input-output study were employed to correct for f.o.b. valuation practices.

Nontariff distortions were handled in a number of different ways. For example, tariff equivalents were computed for the commodities affected by the domestic price support provisions which maintain domestic market prices above competitive world markets levels. In most cases the tariff equivalents were determined by finding the ratio of the U. S. export subsidy to the domestic price net of the subsidy. For importables, the tariff equivalent was computed as the percentage difference between domestic and competitive import prices.

The 1958 excise tax rates were calculated from supplementary input-output data showing the distribution of excise taxes by consuming sectors. The corresponding tax rates for 1963 and 1968 are based on Internal Revenue data giving changes in rates on various taxed items.

Total nominal rates for the input-output sectors were obtained by weighting the tariff and nontariff rates for individual products by their relative importance in domestic output. Similarly, whenever aggregation was necessary, domestic output values were used to construct average tariff and nontariff rates.

The Value, Cost, and Efficiency of American Food Aid*

Per Pinstrup-Andersen and Luther G. Tweeten

Theoretical frameworks were developed to estimate the value to recipient countries of food aid relative to untied cash aid, the cost to the donor country, and the social gain realized by channeling surplus productive capacity in the agricultural sector into food aid rather than reducing production. On the basis of these frameworks, the value, cost, and social gains associated with U. S. food aid during 1964-1966 were estimated. The value to recipient countries of food was estimated to be 80 percent of its world market value. The present value of repayments, interest payments, and transportation costs payable by food aid recipient countries was found to exceed the actual value of food aid under the prevailing dollar credit programs. Hence, a net transfer of resources from developing countries to the United States was found to occur. The cost to the United States of maintaining food aid programs during 1964-1966 was estimated to be approximately equal to the cost of reducing production by a similar amount, using voluntary land retirement programs. It was found that evaluation and pricing of U. S. food aid on the basis of the prevailing export prices results in a considerable overstatement of the actual value to the recipient countries and causes unduly high repayment obligations.

Knowledge of the value to recipient countries of food aid relative to the value of other types of aid, as well as the opportunity costs to the United States of the two types of aid, is necessary to determine an optimum mix of food and nonfood items in U. S. economic assistance programs as well as an optimum allocation of U. S. food surpluses.

It is often assumed that food aid valued at domestic prices or at export prices provides benefits to the recipient country equivalent to aid in any other form. Likewise, it is often assumed that food aid entails little or no resource cost to the United States because surplus capacity exists in agriculture.

Clearly the concept of opportunity cost is central to an economic evaluation of food aid. A few studies have recognized this. Tweeten [13] developed a theoretical framework that specifies (a) the optimal allocation of resources between providing farm commodities versus other forms of aid to developing countries and (b) the optimal combination of production control and disposal in foreign countries as a means of handling reserve capacity in U. S. agriculture. The model can be used to determine the optimal combination of food aid, nonfood aid, and voluntary domestic production control at a given government cost, either (a) to maximize domestic net farm income while holding the real level of foreign aid constant or (b) to maximize real foreign aid while holding domestic net farm income constant.

Pincus [7] estimated the cost of the various types of U. S. foreign aid and Hillman and Loveday [1] suggested a theoretical framework to estimate the optimal combination of surplus disposal and supply control. Furthermore, Schultz [11] estimated the aggregate value in the late 1950's of U. S. farm surpluses to recipient countries.

The theoretical models developed in previous efforts must be substantially extended to facilitate a comprehensive empirical analysis. The major objectives of this study are:

(1) To develop a conceptual framework to estimate the value to recipient countries of food aid relative to untied cash aid and to estimate the value of U. S. food aid by means of this framework for 1964–1966.

(2) To develop a conceptual framework to estimate the cost to the donor countries of food aid relative to the best alternative outlet for surplus commodities and to estimate the cost of U. S. food aid on this basis for 1964–1966.

(3) To estimate the social gain associated with food aid programs and its distribution between donor and recipient countries for 1964–1966.[1]

Following a discussion of the data sources, we present empirical estimates of the real costs and benefits for the three major types of U. S. food aid (grants, credit sales, and nonconvertible currency sales) and for the total actual 1964–1966 aid comprised of these three types. The conceptual framework for each estimate

* The authors appreciate very much the observations on the original manuscript made by James Plaxico, Leo Blakley, and Dean Schreiner.

Per Pinstrup-Andersen *is an agricultural economist for the Centro Internacional de Agricultura Tropical at Cali, Colombia. Luther G. Tweeten is professor of agricultural economics at Oklahoma State University.*

[1] The social gain is defined as the value of food aid to recipient countries less its value in its best alternative use.

is presented with the empirical results; a more rigorous conceptual framework is found in the Appendix.

Data Sources

The basic data were obtained from a mail survey covering 14 countries. All countries that received one percent or more of the total U. S. food aid during 1964–1966 were included in the sample, provided that they had diplomatic relations with the United States when the research was initiated. The survey countries received 70 percent of total U. S. food aid during 1964–1966.

Potential individual contacts were chosen after consultation with a large number of individuals and agencies, some American and some in the sample countries. Only individuals with a considerable knowledge of economic development and external economic assistance programs and needs were included. Of the 441 persons contacted, a partly or fully completed questionnaire was received from 88, an overall response rate of 20 percent. Some of the 88 replies represented joint responses. Of the 88 respondents, 72 were citizens of the countries surveyed and 16 were U. S. citizens. The latter were foreign development experts living in the survey countries. Of the former, 46 were economists and/or political scientists, most of them affiliated with universities; 7 were cabinet members; 8 were government officials; 11 had other professions.

The questionnaire covered a number of aspects of U. S. foreign assistance programs. Only those results that refer to the value of food aid are reported here.[2]

Each survey participant was asked to indicate for three levels of food aid for 1964–1966 the amounts of untied cash aid that he believed would have been of equal benefit to the particular country. The three levels of food aid were (1) the actual amount received valued at world market prices, (2) an additional amount of $1 million annually, and (3) an amount 25 percent above that actually received. The *average value* of food aid was estimated as the inverse ratio of the actual amount of food aid to the amount of equivalent untied cash aid indicated.

The untied cash aid believed to be of the same benefit as an additional $1 million of food aid may be interpreted as the marginal value of food aid where the marginal unit is $1 million. The cash aid equal to a 25 percent increase in food aid may be interpreted similarly. Assuming that the marginal value per dollar of food aid was a linear function of the quantity of food aid which might have been received beyond the actual amount, the *marginal value* (the value of the last dollar of food aid received) was then estimated by means of linear regression.

How efficient was the sample? Some indication can be obtained by computing standard errors—the clustering of responses about the mean. The standard errors were computed for estimates of the marginal value of food aid as a percentage of the export value for eight countries from which five or more questionnaires were obtained.

The standard errors ranged from 5.8 percent for Brazil to 8.8 percent for Chile. We believe these figures reflect considerable agreement among respondents. Of course, a small error does not rule out bias; respondents could have consistently overestimated or underestimated the value of food aid.

While shortcomings of data suggest caution in interpreting results, we believe the estimates to be useful. Furthermore, we are unaware of other comprehensive estimates of the value of food aid. Finally, we are unaware of any alternative methodology that would offer more reliable estimates of the value of food to recipient countries at a manageable research cost. While these estimates are neither final nor exact and further refinements are desirable, the estimates do reflect the views of selected and presumably informed foreigners and Americans about the value of U. S. food aid.[3]

Average and Marginal Value of Food Aid to Recipients

Table 1 shows the estimated marginal and average value of U. S. food aid for each of the survey countries. Each estimated value shows the worth of food aid to the recipient country as a percentage of the face value[4] of the aid at the margin and on the average, respectively.

The estimate for each country was weighted by the amount of food aid received to obtain the weighted mean of the country averages.

[2] For a discussion of findings on the impact of food aid on commercial food export, see [9].

[3] For a more complete presentation of primary and secondary data sources and limitations, see [8].

[4] Face value is defined as the value determined on the basis of prevailing world market prices.

Table 1. Estimated value of U. S. food aid in percent of prevailing world market prices and the aid components present for each of the survey countries, 1964–1966

[a] The survey countries are ranked according to the amount of food aid received during the three fiscal years 1964–1966. For the amounts see [8].
[b] The cost of transportation is shown as a percentage of the value of the food aid on the basis of prevailing world market prices. The rates on foreign vessels are used.
[c] See Appendix equations (1)–(9) for aid component formulas.
[d] It is assumed that the U. S. requirements for nonconvertible currencies are satisfied prior to the receipt of the last unit of currency.
[e] It is assumed that the same proportion of the last unit of currency is used in place of dollar spending as for all previous units.
[f] Average aid components. The aid components in grants is included in the actual program mix but is not listed in separate columns because the estimates are the same as those in the columns labeled "average value" and "marginal value."
[g] Blanks indicate that the estimate was not available.

This weighted average for 11 countries was estimated to be 80 percent on the average and 77 percent at the margin (Table 1). This implies that the survey countries would have been equally well off during 1964–1966 receiving either the actual amount of food aid as donations or an amount of cash aid equal to 80 percent of the world market value of the food aid.

The Aid Component

To perform realistic evaluations and comparisons of various types of foreign assistance programs, a universal unit or common denominator is needed. The common denominator used here is the aid component. The aid component present in foreign economic assistance is defined as the real value of the gross flow of money, goods, and services to a recipient country less the discounted present values of the required disbursements (repayments, etc.).[5]

Grants

The aid component included in food grants consists of the real value[6] of the food less transportation costs payable by recipient countries. Under the grant program the total cost of transportation is paid by the United States. Since no other disbursements are required of grant recipients, the average and marginal aid components expressed as a percentage of the face value of the aid are equal to the average and marginal values, respectively, as shown in the first two columns of Table 1.

Sales on long-term dollar credit

The aid component present in sales on long-term dollar credit may be expressed as the real value of the food received less (a) transportation costs payable by the aid recipient and (b) the discounted present value of down payment, principal repayments, and interest payments (see Appendix). Most agreements under this program are based on either a 20-year or a 40-year repayment period, with a grace period of 2 and 10 years. A down payment of 5 percent of the total value of the commodities is stipulated. The interest rate is 2 percent during the grace period and 2.5 percent of the unpaid balance during the remaining years.

The present value of disbursements was calculated for each of the two credit arrangements using a discount rate of 6.5 percent and a 10 percent rate of default.[7] The estimated aid components expressed as a percentage of the

[5] Disbursements, as applied in this case and in later analyses, refer to the total payment required from aid recipients, including transportation costs if paid by aid recipients.

[6] The real value is given by the average value of food aid, as previously estimated, multiplied by the face value of the total aid provided under the particular aid program.

[7] See Appendix for a discussion of the choice of interest rate and rate of default.

face value are presented in Table 1. The aid component was small and varied considerably among countries. This is due to differences in the need for food relative to other types of aid, the aid terms, and the transportation cost.

In general, the aid component present in the last unit of food aid was found to be lower than the average aid component. This implies that, given the prevailing amounts of food and nonfood aid, the efficiency of food aid relative to other types of aid is decreasing as food aid is expanded.

A negative average aid component in Table 1 implies that if the countries have access to loans carrying a rate of interest of 6.5 percent, they would have been better off rejecting food aid on long-term dollar credit.

The weighted mean of the average aid component for the survey countries was found to be −6.8 under the 20-year terms. This means that the recipient countries paid 7 cents more for each dollar's worth of food, where worth is expressed by prevailing world market prices, than its real value to them. The recipient countries would break even, i.e., the aid component would be zero if the countries paid back only three-fourths of the credit—a default rate of 25 per cent.

Sales for nonconvertible currencies

The aid component present in sales of U. S. food for nonconvertible currencies is defined as the real value of the food less (a) transportation costs payable by aid recipients and (b) the amount of dollar spending in the recipient country displaced by the local currency obtained (see Appendix).

The aid component is considerably larger for food sold for nonconvertible currencies than for food sold on dollar credit, according to results presented in Table 1. The average aid component present in U. S. food aid sold for nonconvertible currencies during 1964–1966 was estimated to be 36.7 percent of the face value of the aid. The aid component present in the last unit of aid was estimated to be 57.6 percent of the face value if it is assumed that the U. S. requirements for nonconvertible currencies are satisfied prior to the receipt of the last unit of currency. If, on the other hand, it is assumed that the same proportion of the last unit of currency is used in place of dollar spending as for all previous units, then the aid component present in the last unit was estimated to be 34.0 percent of the face value. It is likely that the amount of nonconvertible currency replacing dollar spending for any individual country was somewhat fixed and affected little by additional currency in the 1964–1966 period. Thus, the former assumption appears to be more valid.

The actual program mix, 1964-1966

Based on the amount of food aid actually received under each of the three programs, the average aid component was estimated for each of the survey countries and was expressed as a percentage of the face value of the 1964–1966 food aid in Table 1. The survey countries would have obtained the same benefit from 43 cents of untied cash aid as from $1 of food aid during 1964–1966.

It was estimated that India, which was the major food aid recipient during 1964–1966, would have gained equal benefits from either 53 cents of untied cash aid or $1 of food aid. The relatively high real value of food aid to India is partly explained by the high value of food relative to cash aid, as earlier indicated, and partly by the fact that India received all her food aid under two programs, sales for nonconvertible currency and grants, both of which have a high aid component.

Net Costs to the Donor Country

Two alternative outlets for surplus commodities presently exported under aid programs—commercial export and production control—were analyzed in the original study [8].[8] Only production control is included in this article, in order to reduce the volume of material.

The net cost to the United States of food aid if production control is the best alternative outlet for the food included in the programs, may be estimated as (a) the savings that the United States could have realized by reducing production by the amount of food exported under aid programs, i.e, revenue foregone by maintaining the food aid programs, plus (b) transportation costs on food aid payable by the donor country, less (c) the present value of the disbursements made by the aid recipients.[9] (See Appendix for formulas.)

[8] We assumed that any agricultural program would need to maintain farm income; hence, a free market that would allow prices to fall was not considered.

[9] Using as discount rate the average returns from public investment in the United States instead of the previously used World Bank lending rate. Krutilla and Eckstein's estimate of 5.5 percent was used in this study [2].

The estimated net costs for each of the major aid programs are shown in Table 2. The net costs are based on a function describing the relationship between the efficiency of government programs to reduce production and the level of acreage diversion. On the basis of this function, the treasury cost required to reduce farm output by $1.00 could be estimated for any level of food aid. The cost ranged from approximately 25 cents for low acreages to $1.00 at 80 million acres.

Table 2. Estimated net cost of U. S. food aid under each of the various aid programs, 1964-1966[a]

Aid program	Average net cost	Marginal net cost
Sales on dollar credit		
20-year terms	−45.6	−35.6
40-year terms	−38.9	−28.9
Nonconvertible currency	3.0	13.0
Grants	45.9	55.9

[a] The net cost is expressed in percent of the face value of the aid. See Appendix equation (12) for formulas.

The net cost of exporting food under long-term dollar credit was found to be negative; i.e., the present value of the disbursements made by aid recipients exceeds the revenue foregone by not curtailing production. If all food aid were exported on long-term dollar credit and production control were the best alternative, the United States would realize an average gain equal to 45.6 percent of the face value of the aid under 20-year terms and 38.9 percent under 40-year terms by allocating the surplus capacity to foreign aid rather than to production controls.

If all food aid were sold for nonconvertible currency, the net cost to the United States was estimated to be 3 percent of the face value of the aid. Finally, if no disbursements were required, the net cost was estimated to be 45.9 cents per dollar's worth of food aid.

The gains at the margin were found to be somewhat lower than the average gains, primarily because of a negative correlation between the efficiency of U. S. government programs in reducing farm production and the level of reduction attempted.

Social Gain

The average net social gain expresses the net addition to social output obtained by maintaining the food aid programs during 1964–1966 rather than allocating the food aid commodities to the best alternative use. If production control were considered the best alternative, the estimated average net social gain realized by maintaining food aid programs would be between 39.3 and 33.7 percent of the face value of the aid (Table 3).

Table 3. Estimated average and marginal net social gain of food aid in percent of face value and their distribution between donor and recipient countries, 1964-1966[a]

Aid programs	Average net social gain			Marginal net social gain		
	Total	Aid recipient	Donor	Total	Aid recipient	Donor
Sales on dollar credit						
20-year terms	38.8	− 6.8	45.6	26.1	− 9.5	35.6
40-year terms	39.3	0.4	38.9	26.6	− 2.3	28.9
Nonconvertible currency	33.7	36.7	− 3.0	21.0	34.0	−13.0
Grants	33.7	79.6	−45.9	21.0	76.9	−55.9

[a] See Appendix equations (11)–(14).

The distribution of social gain between donor and recipient countries is shown by the aid component and the net cost. The aid component indicates the net gain obtained by the recipient country. Hence, the net social gain less the aid component indicates the net gain obtained by the donor country. The size of the aid components and the net cost for each program have been discussed previously.

The net social gains realized under credit arrangements exceeded those obtained under other aid programs. This phenomenon is due to imperfections in the international money market. The returns to capital under equal risk is higher in the recipient countries than in the donor country. Hence, the social gains realized under credit arrangements consist of (a) the gains obtained by allocating the commodities to food aid rather than to the best alternative outlet plus (b) the gains obtained by reallocating capital from lower to higher returns.

The net gain obtained by aid-recipient countries indicates the amount of cash aid (grants) that would have had an impact on economic progress equal to the impact obtained by the food aid.[10] Or the net gain may be viewed as the benefit obtained by the recipient countries in excess of the potential benefits available from borrowing an amount of money equal to the face value of the food

[10] In Table 3 the amount of cash aid is given as a percentage of the face value of the food aid.

aid at the rate of interest equal to the discount rate used.

The net gain obtained by the donor country indicates the revenue obtained from surplus commodities used for food aid in excess of the revenue obtainable from the best alternative use of the surplus commodities.

As shown in Table 3, the net social gains are somewhat lower at the margin than on the average. Hence, the contribution of the last dollar's worth of food aid to social outputs is lower than the average contribution.

An Analysis of Total U. S. Food Aid During 1964-1966

Results of an analysis of total U. S. food aid during 1964–1966 are shown in Table 4. The average annual value of the total U. S. food aid during 1964–1966 was reported as $1,569.4 million. Since the value of grants is reported on the basis of total CCC costs, the face value of the aid, i.e., the value based on prevailing export prices, was somewhat smaller—$1,473.7 million. Assuming that the average rate of substitution for major aid recipients shown in Table 1 is valid for all U. S. food aid, the real value to the recipient countries was an estimated $1,173.1 million per year. However, disbursements were required.

The present value of down payment, repayments, and interest payments was estimated at $418.6 million annually when the estimation was based on a discount rate reflecting alternative cost of capital to recipient countries and $430.6 million when based on the U. S. alternative cost of capital.

The cost of transportation paid by food aid recipients was estimated to be $258.9 million annually. This amount covered the cost of shipping food aid commodities received under Title I (dollar credit and nonconvertible currency) on foreign vessel. If the aid commodities were shipped on U. S. vessels, the United States paid the transportation costs in excess of those charged by foreign vessel. We consider these costs to be a subsidy to the U. S. merchant marine independent of food aid considerations. Hence, we did not include them in our calculations.

The United States paid the total shipping cost related to food donations. Using the foreign vessel rates, these costs were estimated to be $25.5 million annually.

The value of aid to recipient countries, less the present value of disbursements and transportation, gives a net value of U. S. food aid to recipient countries totaling $495.6 million annually in the 1964–1966 period (Table 4). This was only 34 percent of the face value of the aid.[11,12]

The government cost of food aid was $1,569.4 million annually for commodity purchases plus $25.5 million for transport costs less the present value of recipients' disbursements, $430.6 million, or $1,164.3 million.

Instead of food aid, the U. S. Government could have chosen voluntary production control. The government cost of reducing production by an amount equal to that shipped under PL 480 during 1964–1966, while leaving U. S.

Table 4. Reported value, cash equivalent, net cost, and social gain of total U. S. food aid, 1964-1966

	Percent of face value	Annual average (*million dollars*)
Reported value[a]	106.5	1,569.4
Face value[b]	100.0	1,473.7
Value to recipient countries	79.4	1,173.1
Disbursements required (United States)[c]	29.2	430.6
Disbursements required (Recipients)[d]	28.4	418.6
Cost of transportation (paid by United States)	1.7	25.5
Cost of transportation (paid by recipients)	17.6	258.9
Cash equivalent (aid component)	33.6	495.6
Revenue foregone[e]	28.3	417.5
Net cost to the United States	.8	12.4
Social gain	32.8	483.0

[a] As reported by U. S. Government.
[b] Evaluation based on prevailing export prices.
[c] The present value of down payment, repayments, and interest payments, using as discount rate the alternative cost of capital to the United States.
[d] As above, except that the discount rate reflects the alternative cost of capital to aid-recipient countries.
[e] Assuming that production control was the best alternative outlet for excess productive capacity.

[11] The difference between the estimated aid component for the survey countries and that for the total aid is due to a considerable difference in the proportion of the nonconvertible currency used to replace dollar spending in the survey countries and the countries not surveyed.

[12] Transportation costs were subtracted from the gross to arrive at this net value because other forms of real aid would have required less transportation cost per dollar of real aid (e.g., technical assistance). If transportation costs are excluded under the assumption that they would accrue in equal magnitude under all forms of real aid, then the cash equivalent value of foreign aid was 51 percent of the reported value of the aid.

net farm income unchanged, would have been \$1,151.9 million annually.[13]

Thus, the net cost to the United States from PL 480 rather than production control was \$1,164.3–\$1,151.9 = \$12.4 million, or .8 percent of the face value of food shipments.

Conclusions

The results obtained in this study indicate that the use of U. S. food, feed, and fiber "surpluses" as foreign aid during 1964–1966 resulted in a greater contribution to world social output than if production had been reduced.

The distribution of the net social gain between donor and aid recipients was determined by the terms of the aid. It was found that the entire net social gain accrued to the recipient countries if the food aid was traded for nonconvertible currencies or received as donations. In addition, a net transfer of resources from donor to recipient countries was estimated to have taken place under these programs. Conversely, under credit arrangements, the U. S. obtained the entire net social gain. Furthermore, it was found that unless the rate of default of the credit was high, a net transfer of resources from the aid recipient countries to the donor country would take place. This finding appears to contradict conventional knowledge and beliefs on which foreign economic assistance programs are based. If foreign aid is defined as a net transfer of resources from a more developed country to a less developed country, the long-term dollar credit arrangements do not qualify as aid programs, according to the results from this study.[14]

The use of the value of food aid, as currently reported, as an indicator of the flow of actual aid to developing countries is very misleading. Neither prevailing export prices nor CCC costs reflect the real value of food aid to recipient countries. Nor are the required disbursements from aid recipients taken into consideration.

Prevailing export prices or CCC costs utilized as value indicators for food aid misinform the public and can lead to a smaller total flow of real aid to developing countries than would be desired by the U. S. public. From the point of view of the U. S. legislators, the reported value of the aid flow indicates the actual aid contribution. However, if the reported value is inflated, the amount of real aid is less than what the legislators were actually willing to contribute. If the value of food aid is not correctly reported, other types of aid may be misallocated. Furthermore, the share of the total economic assistance provided by any one donor country may not be correctly reported. For a country where the ratio of food to nonfood aid is high, the reported share is upward biased, ceteris paribus. The same problem exists in nonfood aid where the face values of loans and grants are lumped together as "aid."

One way to provide correct information concerning the value of foreign aid flows would be to evaluate and report all foreign economic assistance on the basis of the value to recipient countries less the disbursements required, i.e., the aid component—the amount of untied cash aid (convertible currency) of equal benefit to recipients.

Pricing of commodities exported under aid programs that require repayment either in nonconvertible currency or dollars, on the basis of prevailing world market prices, causes unduly high repayment obligations.

It is suggested that repayments of food aid be based on the revenue foregone by the donor country by allocating the commodities to food aid rather than to the best alternative use, e.g., production control. This would preclude a net reverse transfer of resources. Furthermore, the total social gain would be obtained by the aid recipients. The real cost to the donor country would be limited to the difference between the interest charged on the credit and the opportunity cost of capital.

Because of increasing emphasis in export on long-term dollar credit (a program that may have a negative aid component) it appears that correct pricing and evaluation of food aid in the future is extremely important if a high degree of efficiency in foreign economic assistance is to be obtained.

Appendix

The following analysis expresses mathematically a number of concepts used in the text, including the aid component, the net social cost, and the net social gain.

[13] The cost associated with voluntary production control is given by the cost of commodity purchased, \$1,569.4 million, less revenue foregone, \$417.5 million.

[14] The developing countries' acceptance of aid programs with a negative aid component may be due to lack of information or to the weak bargaining position of these countries. The only alternative to accepting the food aid may be mass starvation. Furthermore, the recipient country may be preoccupied with the short-run situation; hence, the amount of repayment may be of little significance at the time of the aid transaction.

Aid component in long-term dollar credit sales

The aid component present in sales on long-term dollar credit may be expressed as the real value of the goods received less transportation costs payable by the aid recipient and the discounted present value of down payment, principal repayments, and interest payments.

Let Q be the quantity of food involved in a trade transaction and P_w the world market price in dollars per unit prevailing at the time of trading. Then QP_w is the face value of the commodities traded in dollars. The estimated average value of food aid expressed as a percentage of world market value is called AV and the estimated marginal value of food aid called MV. AV and MV are estimated on the basis of a survey, as discussed in the section on data sources.

If the discounted present dollar value of down payments, repayments, and interest payments is PV, then the total aid component A_1 present in the 1964–1966 food aid is

$$A_1 = QP_w(AV) - T_1 - (PV) \tag{1}$$

where T_1 is transportation costs payable by recipient countries. The aid component at the margin A_2 for 1964–1966 food aid is

$$A_2 = QP_w(MV) - T_{1M} - (PV_M) \tag{2}$$

where T_{1M} and PV_M refer to the marginal unit.

The average aid component expressed as a percentage of the face value of the credit is

$$a_1 = \frac{A_1}{QP_w}100 = AV - \frac{(T_1 + PV)}{QP_w}100. \tag{3}$$

Likewise, the marginal aid component as a percentage of the face value is given by

$$a_2 = MV - \frac{(T_{1M} + PV_M)}{QP_w}100. \tag{4}$$

Various formulas express the present dollar value (PV) of disbursements under various circumstances. It is assumed that the world market prices prevailing at the time of trading are used to determine the amount of credit to be repaid (QP_w). This is usually the case for transactions under PL 480.

Since there may be some doubt as to the ability of the recipient countries to repay the credit obtained on commodities for direct consumption, a coefficient indicating the expected rate of default (D) is included in the computations. The coefficient indicates the expected percentage of the credit that will not be repaid. As the default rate increases, the aid component included in the credit will increase, ceteris paribus.

One reason for including a default rate (rather than including the risk element in the discount rate r) is that the probability of complete repayment of long-term credit on commodities for direct consumption may be smaller than the probability of complete repayment of loans for investment purposes. By introducing the default rate to cover only the difference in risk between investment loans and consumption credit, the discount rate r is directly comparable to the opportunity cost of capital for investment purposes. Thus, the World Bank's lending rate of 6.5 percent may be used as the rate of discount.

At the time of the study the credit arrangements had been recently introduced. Available historical evidence did not lend itself to a projection of the future rate of default.

A model was developed to determine the aid component as a function of the default rate. Hence, although the results reported here are based on an arbitrary selected default rate of 10 percent, estimates based on other default rates may be easily obtained. A 1 percent increase in the default rate increases the aid component approximately .5 percentage points for the 20-year arrangement and .2 percentage points for the 40-year arrangement.

The default rate is introduced into the model with the assumption that the probability of default is the same for any one year during the repayment period. There is some indication that defaults usually are limited to the repayments of principal. We assumed that all interest payments will be paid on time.

The present value of down payment, repayment of principal, and interest payment for a loan with a grace period of n' years and a total duration of n years is given by

$$\begin{aligned} PV = {} & i_1(QP_w - I)[(1+r)^{n'} - 1] \\ & [r(1+r)n']^{-1} + I + \sum_{t=n'+1}^{n} \\ & \Big[[(QP_w - I)(1-D)](n-n')^{-1} \\ & + i_2(QP_w - I) \\ & [1 - (t - n' - 1)(n - n')^{-1}] \Big] \\ & (1+r)^{-t} \end{aligned} \tag{5}$$

The first part of the equation relates to the

interest payment during the grace period, I is the down payment and the remaining terms include the interest and repayment of principal during the repayment period $n-n'$.[15]

The rate of interest during the grace period and repayment period is given by i_1 and i_2 respectively and r is the discount rate.

The remaining variables were defined previously.

Aid component in sales for nonconvertible currencies

The aid component present in sales of U. S. food for nonconvertible currencies consists of the actual value of the food less transportation payable by aid recipients and the amount of dollar spending in the recipient country displaced by the local currency obtained. An estimate of the total aid component included in sales for nonconvertible currencies is

$$(6) \qquad A_1 = QP_w(AV) - T_1 - B$$

where Q, P_w, T_1, and AV are as previously defined and B is the amount of dollar spending displaced by local currency in the recipient country.

The aid component at the margin is given by

$$(7) \qquad A_2 = QP_w(MV) - T_{1M} - (MB)$$

where MB is the amount of dollar spending substituted by the local currency obtained at the margin.

Aid component in grants

The aid component included in food grants consists of the real value of the grant less transportation costs payable by recipient countries. As before, the real value is estimated by the average value of food relative to untied cash aid. Thus, the aid component present in food grants is

$$(8) \qquad A_1 = QP_w(AV) - T_1.$$

The aid component at the margin is

$$(9) \qquad A_2 = QP_w(MV) - T_{1M}.$$

Net costs of food aid to the donor country

Ignoring government storage costs, the revenue foregone per dollar's worth (world market price) of food aid may be estimated as the treasury cost required to purchase one dollar's worth (world market price) of surplus commodities less the treasury payment necessary to reduce the quantity produced by an equal amount. The net cost may be estimated as

$$(10) \qquad NC_{PC} = \frac{P_R}{P_w}(1 - C_{PC}) + T_2 - (PV)/QP_w$$

where

NC_{PC} = net cost per dollar's worth of food aid if production control is the best alternative outlet for surplus commodities;

P_R = prices received by farmers, weighted average for the commodities involved;

C_{PC} = treasury cost required to reduce the quantity produced by an amount that, valued at prices received by farmers, is worth one dollar;

T_2 = transportation cost payable by the donor country pèr dollar of food aid.

Other notation is as defined before. The price ratio (P_R/P_W) was calculated for each of the major food aid commodities. To obtain the price ratio corresponding to food aid, each of the commodity price ratios was weighted by the amount of the corresponding commodity exported under food aid programs during 1964–1966.

Net social gain and distribution

The average net social gain ASG obtained from food aid programs may be defined as the value to the recipient country of the aid in excess of the value of the food in its best alternative use less the cost of transporting the food from donor to recipient country. Hence, the average net social gain expressed as a percentage of the face value of the aid is given by

$$(11) \qquad ASG = AV - RF - (T_1 + T_2)$$

where RF is the revenue foregone as a proportion of the face value, and T_1 and T_2 are the transportation costs per dollar of food aid paid by the recipient and donor countries, respectively. AV was defined previously.

Equation (11) may be rearranged as follows:

$$(12) \qquad ASG = (AV - T_1) - (RF + T_2).$$

If the present value of repayments PV is

[15] A complete mathematical description of the development of the model may be found in [8] or obtained directly from the authors.

subtracted from each of the two terms on the right-hand side of equation (12), the result is

$$ASG = a_1 - NC_{PC} \tag{13}$$

where a_1 is the average aid component, as in (3); and NC_{PC} is the average net cost as a proportion of the face value, as in (10).

If the present value of repayments is not equal for donor and recipient countries, the latter equation yields an estimate of ASG that is different from the former. This may be the case for export on long-term dollar credit. The opportunity cost of capital in the recipient countries may differ from the opportunity cost in the donor country under equal risk because of imperfections in the international money market. Therefore, two different discount rates would be applied.

The adjustments in the social gain due to differences in the opportunity cost of capital are taken into account in the latter formula but not in the former. Hence, the latter formula is most appropriate for estimating the net social gain.

The marginal social gain MSG as a proportion of the face value of aid may be estimated as

$$MSG = a_2 - MNC_{PC} \tag{14}$$

where a_2 is marginal aid component, as in (4); and MNC_{PC} is the marginal net cost as a proportion of the face value of aid.

Tax in Kind to Reduce Supply and Increase Income Without Government Payments and Marketing Quotas*

EARL O. HEADY

Theoretically, a tax in kind can be used to reduce supply and increase net farm income. Applied through a share payment to government, private marginal costs are increased and supply is decreased. The government also has a food fund to be used for aid or similar purposes. The mechanism requires neither government payments nor compulsory market quotas to lessen supply. However, compulsory sharing is necessary to prevent "free riders." Variants of the mechanism would include a gross sales tax collected in conjunction with income taxes. The mechanism provides a policy alternative with interesting potentials in income distribution.

THIS PAPER includes a theoretical discussion of a policy mechanism that has features of supply restraint and price improvement. However, in contrast to present farm programs (which use public payments to encourage voluntary supply control) and marketing quotas (mandatory imposition of producer quotas), the mechanism can attain the same level of supply control and price improvement with neither government payments nor imposed marketing quotas. Further, at least theoretically, the method places no restraints on freedom in farmer choice and decision, and the farmer's contribution to supply control and price improvement is roughly proportional to his gain. Finally, the mechanism has the same consumer effects (i.e., levels of food prices and progressiveness of food costs relative to income) as any other program (e.g., present land retirement programs or marketing quotas).

The proposal is applicable to all agricultural commodities with price elasticities of demand less than unity and supply elasticities greater than zero. Of course, the major commodities to which supply control and price support programs have been applied over the last four decades fall in this category.

The analysis is presented to help extend the continuous farm policy debate. It is not presented as a practical program ready for "application tomorrow." However, with additional experience of farmers in market management, commodity check-offs, marketing boards, and similar devices, it is a mechanism that could have interest, acceptance, and lower public costs. It has some features that are the equivalent of monopoly selling organizations, such as the marketing boards of Australia, Canada, and New Zealand. Meyers has presented a somewhat similar example where increased costs can result in greater profits [2].

The system is one which, theoretically, might be managed either by farmers or by government. As a farmer-managed mechanism, the farm sector could hold a "food fund" under one of the variants. The implied method of obtaining this food fund could reduce domestic market supply and bolster prices and income and also allow the farm sector to appeal to humanitarian purposes (improve public relations through the betterment of the world's hungry and poor people). The food fund under this variant could be offered to populous and less developed countries at no cost if they paid transport and handling costs (and insulated the added supplies from the market to prevent price depression for the country's producers). While the system could be farmer-managed, in the discussion that follows we suppose government to serve as the implementing agency and that legislative or other means are provided to effectuate the "sharing arrangement." The program would have to apply to all major commodity producers to prevent "free riders."

The proposed mechanism is logically simple and is only a variant of a present program mechanism. Under current acreage control programs, and through the equivalent of a cash rental payment, the government "rents" the land from the farmer or landowner and devotes it to the desired use (i.e., fallow or nonproduction). The proposed mechanism is in the same framework, except that the relationship is reversed, the government now serving implicitly as "the landlord" and the farmer as "tenant." However, the government (or a "farmer mar-

* Journal Paper J-6670 of the Iowa Agricultural and Home Economics Experiment Station, Project 1759. I am indebted for some extremely useful comments to Dale Hoover, Robert S. Firch, and two unidentified referees. Robert Crown also has provided important modifications.

keting board") does not become the owner but receives only a share of output. In contrast to the present system wherein the government (as tenant) pays a cash rent to the farmer (as landlord), the farmer now (as tenant equivalent, but still the owner and independent decision-maker) pays a share rent to the government (as landlord equivalent). We use this terminology to indicate that the proposed mechanism is in the framework of present programs, with only an inversion of farmer and government roles and substitution of payments in kind for payments in cash. Theoretically, but also expected in practice, a sharing of the farmer's output with government (or a farmers' marketing board) should reduce supply and raise prices and income. But this could be accomplished at no cost to government. We analyze two cases: (a) where government might use its share for international food aid, with the acquisition costs of the commodities for shipment of food aid being zero (but having the effect of reducing domestic supply and raising prices and income); (b) where the government places its share in the domestic market, but total marketed supply is decreased (as compared to no program).

The first of these alternatives increases farm costs because more is produced; but since a share is withheld from the market, prices and total revenue increase proportionately more. Under the second method, total farm costs decrease; and price, total revenue, and aggregate profits to producers increase. Hence, the system has versatility and diversity, at least in its basic theory and logic and in other possible variants. In economic effect, the program could be applied to single commodities without close substitutes, to commodity groups that embrace all close substitutes or all commodities of the farm sector.

The share of product could perform another role if the system were self-managed by farmers. (Government legislation and authority would be essential to create the program, but farmers could manage it.) Most farm organizations re-require monetary dues from their members. Hence, rather than a cash payment, the product share explained later would serve as "due payments in kind" but also would serve simultaneously as the mechanism which reduces output and increases prices and income. Some farm organizations already use a "check-off" system. Typically the check-off is employed to obtain funds for product promotion and is too small to affect supply. The method explained below would be the equivalent of a check-off system, but requires a much larger share and would have objectives of raising producers' prices and incomes through its effect in restraining supply.

A similar result could be obtained through a gross sales tax. If collected from farmers as a percentage of sales price for commodities under the program, in conjunction with the federal income tax, the program not only would, theoretically, attain goals heretofore specified but also would have much lower administrative costs than any other program. (Our tax in kind would still require "policing" to guarantee that each farmer pays his "honest share" and "free riding" is prevented.) If the share rent were commuted to cash, complexities surrounding the intermediate and final nature of various agricultural products would be lessened. The government then could use the revenue so obtained to buy food for aid shipments. In another variant of the general approach, the government could withdraw all "rights" for production of agricultural commodities. Farmers would then buy these rights at a price paid per unit of output at the outset of the production season (so that capital requirements are increased during the production period). The level of the price, paid for the "right to produce," would determine the level of supply and income improvement. However, it might be more difficult to convince farmers that a "price for the right to produce" would benefit them as readily as an output share contributed to the government to lessen supply. Both systems have interesting implications in income distribution through variations in rates paid by farmers with different volumes or sizes. We analyze its effect on market revenue, output, and income distribution elsewhere [1].

Assumptions and Nature of Model

To illustrate the rationale of the proposal, we turn to a simple algebraic example and use a naive model which is hybrid in its degree of generality and numerical reference. Later we make a geometric summary. The results would be the same regardless of the algebraic relationships employed as long as we refer to commodities with price elasticities for demand of less than unity and for supply of greater than zero. The method would apply to all commodities with these characteristics. However, to maintain simplicity, we refer to a single commodity and a single agricultural resource to reflect

production and cost relationships. The numerical parameters used, to provide a degree of specificity, slightly overstate the conditions surrounding agriculture but are used for purposes of emphasis and do qualitatively describe the market economy.

We suppose the demand function:

$$P = \beta Q_d^{-2} \tag{1}$$

where the price elasticity is $-.5$, β reflects income, population, and consumer preference components of demand while P and Q_d are respectively the market price and quantity variables. Supposing n farms each with the same production function and each producing n^{-1} proportion of the total, the aggregate production of the producing sector is

$$Q_p = \alpha X^{1/2} \tag{2}$$

where Q_p is output and X is a variable resource (or a collection of variable inputs used in a given mix). Under assumptions of perfect knowledge and profit maximization objectives, the sector's total cost function is (3) and its marginal cost function is (4) where P_x is the price of inputs:[1]

$$TC = \alpha^{-2} P_x Q_p^2 \tag{3}$$

$$MC = 2\alpha^{-2} P_x Q_p \tag{4}$$

Equating marginal cost to price and setting quantity dependent, the commodity supply function is

$$Q_s = .5\alpha^2 P P_x^{-1} \tag{5}$$

In an overly simplified context of a simultaneous supply and demand period, the demand function in (1) and the supply function in (5) are equated to generate equilibrium market price and quantity, farm revenue, total costs, and net profit. So computed, the quantities reflect the situation (as denoted by the subscript o) in the absence of any policy to modify supply. Market price is expressed in (6), equilibrium output quantity in (7), total revenue in (8), total costs in (9), and net profit of the farm sector in (10):

$$P_0 = 2^{2/3}\alpha^{-4/3}\beta^{1/3}P_x^{2/3} \tag{6}$$

$$Q_0 = 2^{-1/3}\alpha^{2/3}\beta^{1/3}P_x^{-1/3} \tag{7}$$

$$TR_0 = 2^{1/3}\alpha^{2/3}\beta^{2/3}P_x^{1/3} \tag{8}$$

$$TC_0 = 2^{-2/3}\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \tag{9}$$

$$\pi_0 = (2^{1/3} - 2^{-2/3})\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \tag{10}$$

In the equations above and those that follow, we retain fractional forms of exponents and keep separate the numerical multipliers in order that others who wish to adapt the analysis further can minimize the arithmetic in doing so.

Implementation of the Policy

Given the price and income quantities under market equilibrium above, we now implement the policy mechanism to reduce supply and improve prices and income. To do so, the government requires a .2 share of total production (an amount of production equal to .25 proportion of the farmers' share).[2] Under these shares, the production and demand functions remaining the same, the farmers' total cost function and the aggregate supply function now become (11) and (12) respectively (the latter derived from the marginal cost function conforming with TC_0' as explained in footnote 2). The market supply, Q_s', is the farmers' share only.

$$TC_0' = 1.25^2\alpha^{-2}P_x Q_P^2 \tag{11}$$

$$Q_s' = (.5)(1.25^{-2})\alpha^2 P P_x^{-1} \tag{12}$$

Equation (11) is the total cost function of the marketed share of output. Of course, the total cost function of total output (farmers' marketed share of .8 and government's share of .2)

[1] The total cost function is derived from the production function in this manner: Inputs required as a function of output are

(a) $$X = \alpha^{-2} Q_p^2$$

and the total cost of inputs is

(b) $$TC = P_x X$$

Now, by substituting the input relationship of (a) for X in equation (b), the total cost function is expressed as equation (3).

[2] When the farmer must give a .2 share to the government (or "farmers' board"), the farm share of the production function is

(c) $$Q_p = .8\alpha X^{1/2}$$

and the input equation is no longer (a) in footnote 1, but becomes

(d) $$X = 1.25^2\alpha^{-2}Q_p^2.$$

Substituting this value of X into the cost function of (b) in footnote 1, the farm total cost function becomes (11) and the corresponding marginal cost function is

(e) $$\frac{d(TC)}{dQ_p} = 2(1.25^2)\alpha^{-2}P_x Q_p.$$

This same marginal cost function for farmers' share prevails for the situation in which the government market is .2 share.

does not change. The private marginal cost curve of the farmer is raised (to equation (e) in footnote 2, from equation (4) in the text), although the social or true marginal cost for total output is not changed. However, since farmers base their decision on their private marginal costs, the supply function then is changed from equation (5) to equation (12).

The government, which receives .2 of total output or $.25Q_s'$, ships its share as food aid to other countries that are insulated from the domestic market. With the modified supply under government sharing of output, supply in (12) and demand in (1) are now equated. A new market equilibrium is created and the corresponding commodity price, supply quantity, farm revenue, total farm costs (at the equilibrium output of Q_1) and net profits are those respectively in equations (13), (14), (15), (16), and (17):

$$(13)\qquad \begin{aligned} P_1 &= (1.25^{4/3})(2^{2/3})\alpha^{-4/3}\beta^{1/3}P_x^{2/3} \\ &= 1.25^{4/3}P_0 \end{aligned}$$

$$(14)\qquad \begin{aligned} Q_1 &= (.8^{2/3})(2^{-1/3})\alpha^{2/3}\beta^{1/3}P_x^{-1/3} \\ &= .8^{2/3}Q_0 \end{aligned}$$

$$(15)\qquad \begin{aligned} TR_1 &= (.8^{-2/3})(2^{1/3})\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \\ &= .8^{-2/3}TR_0 \end{aligned}$$

$$(16)\qquad \begin{aligned} TC_1 &= (1.25^{2/3})(2^{-2/3})\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \\ &= 1.25^{2/3}TC_0 \end{aligned}$$

$$(17)\qquad \begin{aligned} \pi_1 &= \left[(1.25^{2/3})(2^{1/3}) - (1.25^{2/3})(2^{-2/3})\right] \\ &\quad \cdot\alpha^{-2/3}\beta^{2/3}P_x^{1/3} = 1.25^{2/3}\pi_0 \end{aligned}$$

Individual farmers are not restrained in any manner. They can produce to their heart's content (i.e., so that profit is maximized by equating marginal cost with market price—as under the absence of a program). Yet the system results in a marked improvement in price ($P_1=1.25^{4/3}P_0$), market revenue ($TR_1=1.25^{2/3}TR_0$), and profit ($\pi_1=1.25^{2/3}\pi_0$), as market supply is reduced ($Q_1=.8^{2/3}Q_0$). Total costs increase ($TC_1=1.25^{2/3}TC_0$), since the total output (including the government's share) now is greater than the original equilibrium output, Q_o.[3] The share marketed by farmers is Q_1; but since the government receives an amount equal to .25 Q_1, total output is actually 1.25 Q_1 (with .25 Q_1 held from the market) which is larger than Q_o (i.e. total output of 1.25 $Q_1=1.25^{1/3}\,Q_o$).[4] Yet the large increase in price and total revenue, from P_o to $1.25^{4/3}\,P_o$ and TR_o to $1.25^{2/3}\,TR_o$ respectively, more than offsets increased costs and causes net profits to increase, as denoted by comparing π_1 (17) with π_o (10). Not only has the system increased price, market revenue, and net profit, but it also has provided a food fund of .25 Q_1, to use as international aid or for other humanitarian causes, at zero farm level acquisition costs. This is one of the few "have your cake and eat it too" outcomes that can be found in farm policy.

Food Aid Absent

But suppose the green revolution prevails and there are no hungry people in the world to solve the problems of domestic farmers through augmentation of foreigners' diets (or simply suppose that foreign farmers take up arms and prevent commodities from being dumped in their markets to depress price). Or suppose the domestic population has values which prevent the government (or the farmers' own marketing board) from destroying a share of food produced. The system will still work to increase aggregate farm income even with the government marketing its share.

To illustrate, suppose that the government now takes a .2 share of total output and places it on the market. Since the sharing arrangement increases farmers' private marginal costs (for their own share) it also dampens supply and improves price and income. The total cost function (relative to their .8 share) for farmers under this variant is the same as (11). Deriving marginal costs from this total cost function (see footnote 2) and adding the government's share (.2 of the total or a .25 proportion of the farmer share), the total supply function is

$$(18)\qquad Q_s'' = (1.25^{-1})(.5)\alpha^2PP_x^{-1}$$

With demand remaining as (1) and with total

[3] Total output, including the .2 share paid as rent in kind to the government and removed from the domestic market "to be shipped as food aid," is $1.25Q_1$ or $1.25^{1/3}\,Q_o$ (but farmers place only $.8^{2/3}Q_o$ on the market). While the new total output is larger than the previous output, the smaller amount marketed improves price so that even under the share restrained supply function the price effects offset the share effects on total output (but not on marketed output).

[4] The equilibrium output, Q_1, in (14) is generated from the supply function, Q_s', in (12). But Q_1 is only .8 portion of total output. The total equilibrium output is thus $Q_1+.25Q_1$ and the total output corresponding to supply function Q_s', when $.25Q_s'$ is added to denote the government share, is $Q_s'+.25Q_s'=1.25\ (.5)\ (.8^2)\alpha^2PP_x^{-1}=1.25^{-1}$ $(.5)\alpha^2PP_x^{-1}$ which in turn is the same as supply function Q_s'' (farmers output and government marketed share in (18).

market supply (farmer share plus .2 of the total for government) in (18) equated to demand, the market price, equilibrium output, market revenue, total farmer costs (for the equilibrium output), and net profit are given respectively in (19), (20), (21), (22) and (23):

$$(19)\quad \begin{aligned} P_2 &= (1.25^{2/3})(2^{2/3})\alpha^{-4/3}\beta^{1/3}P_x^{2/3} \\ &= 1.25^{2/3}P_0 \end{aligned}$$

$$(20)\quad \begin{aligned} Q_2 &= (1.25^{-1/3})(2^{-1/3})\alpha^{2/3}\beta^{1/3}P_x^{-1/3} \\ &= .8^{1/3}Q_0 \end{aligned}$$

$$(21)\quad \begin{aligned} TR_2 &= (1.25^{1/3})(2^{1/3})\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \\ &= 1.25^{1/3}TR_0 \end{aligned}$$

$$(22)\quad \begin{aligned} TC_2 &= (1.25^{-2/3})(2^{-2/3})\alpha^{-2/3}\beta^{2/3}P_x^{1/3} \\ &= 1.25^{-2/3}TC_0 \end{aligned}$$

$$(23)\quad \begin{aligned} \pi_2 &= \left[(1.25^{1/3})(2^{1/3}) - (.8^{2/3})(2^{-2/3})\right] \\ &\quad \cdot\alpha^{-2/3}\beta^{2/3}P_x^{1/3} = 1.28\pi_0 \end{aligned}$$

The total revenue (21) is that forthcoming from sale of the .8 share of farmers' and .2 share of government's output. Hence, this total revenue is realized by farmers only if the government transfers its .2 share of total revenue back to farmers. The aggregate net profit in equation (23) represents gross revenue to farmers and to the government less farmers' costs of producing the equilibrium output. For the example used, aggregate net profit is 28 percent greater than it would be under absence of the program.

The government cannot return its share of revenue to farmers in proportion to their individual sales because this would cause their private marginal costs of sales value (production) to return to the level in equation (4) and the supply-dampening feature would be destroyed. Hence, in returning its share of sales to the farm sector, the government must use methods that divorce the distribution from current market shares of individual farmers. An opportunity for gain in economic and social goals prevails in this transaction. For example, part of the government's revenue might be returned to farmers (but nonproportionally to output) and the remainder distributed to low-income consumers in order to reduce the "regressive" effects of price improvement. High-income consumers then would bear the burden of increasing incomes of both low-income consumers and farmers-at-large. Under certain conditions of share magnitudes and distribution patterns, the net profit of the farm sector could be increased with (a) some improvement made in the income of all farmers but (b) a greater improvement made in the income of low-income farmers.

As compared to no program, another "eat your cake and have it too" situation arises. Farmers have higher prices, revenue, and profit than under absence of a program, because marginal costs of their own output share are higher and market supply is less. The market price, P_2 in equation (19), is greater than under no program, P_o, but is lower than the price, P_1, when the government exports its .2 share. While the government now markets its .2 share, the equilibrium market supply of Q_2 is still smaller than the original equilibrium supply, Q_o, in the absence of a program.

This formulation of the policy, when compared with the one in which the government insulates its share from the domestic market (shipping it as food aid or simply burying it), indicates lower attainment for farmers. (A program paying farmers not to produce would have lower social costs than if the government destroyed its share under their variant.) However, attainment in price and revenue improvement and supply control is greater than under no program and at no cost to the government. Farmers continue to own their resources and maintain freedom of decision (in contrast to implied mandatory marketing quotas). But, as mentioned previously, the government would need a group of "inspectors" to ensure that all farmers pay their share and that "free riding" is prevented. In other words, compulsory participation would be required but no compulsory quotas or upper bounds on production or marketings would need to be imposed.

Geometric Summary

While not all relevant quantities can be included in a simple geometric presentation, the effect of the mechanism on price, market revenue, and supply quantity is summarized in Figure 1. (A somewhat different algebraic characterization of supply and demand relationships is implied in the figure than in the equations presented previously. Also, the geometric example does not provide an explanation, through marginal costs and supply functions, of how the system works.) The commodity demand function, D, again indicates a price elasticity less than unity. Under the conditions of no program, the aggregate commodity supply function is S_o and market revenue is *Odek*. With the government (or farmers' marketing board) taking the

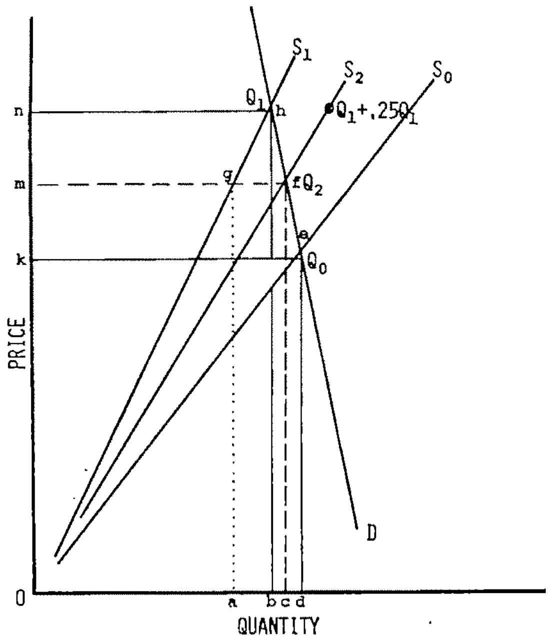

Figure 1. Geometric illustration of effects on price, supply, and market revenue

implied share of the output and withholding it from the domestic market, aggregate supply declines to S_1 and market revenue is *Obhn*, an amount greater than *Odek*. Aggregate commodity supply function S_1 denotes only the quantity marketed by farmers. It does not represent total production at each price. Total output at each price is $1.25S_1$ since farmers get a .8 share and government gets a .2 share of total production. (As explained in footnote 4, S_2 is the "total output function" when the government's share is added, although S_1 is the farmer supply function when .25 S_1 is insulated from the market as the government's share.) However, when the government places its share on the market, total domestic market supply (total production in this case) becomes S_2 and total revenue is *Ocfm*.[5] Since the product share to the government is .2, the government share of total revenue is *acfg* and the farmer share is *Oagm*. If government returns its share to farmers (but in a manner unrelated to output and marginal costs), the total revenue of farmers then becomes *Ocfm*, an amount larger than the original revenue of *Odek* because the sharing arrangement has choked back supply through its effect on marginal costs of the farmers' original share.

Figure 1 also summarizes the relative magnitudes of output under the program variants. The quantity Q_o expresses equilibrium market output. The quantity Q_1 is the .8 proportion of total output marketed by farmers when the government takes its share off the domestic market. (Total output is 1.25 Q_1, with the government removing .2 share of this from the market.) However, when the government markets its .2 share, the equilibrium total output is Q_2. Hence, $1.25Q_1$ is greater than both Q_o and Q_2. Total costs, TC_1, also are greater when the government exports its share than under "no program" or "government marketed shares."

Other Considerations

The mechanisms discussed above provide a rather unique policy instrument for reducing supply, increasing prices and income, and acquiring a food fund for international aid at zero farm costs to the government and without imposition of marketing quotas. Of course, in any actual implementation, the government would have handling and transport costs for its share exported as aid (or used to alleviate domestic hunger); but it has had these costs in all previous programs. If it marketed its share domestically, it would have related handling costs; but because of the smaller output (than under no program), these costs also would be lower and the total net revenue that could be realized by farmers would still increase.

Under real world conditions we would expect farmers to use less fertilizer and other capital inputs if a share of output were handed to the government without a proportionate sharing of costs. The extent to which output would be dampened, or the share required to restrain output and improve prices to particular levels, is unknown. But lack of quantitative knowledge has always prevailed as various policy variables were manipulated in the past. Under the policy mechanism presented, experimentation through implementation also would be required. Under actual conditions of farm supply response (which incorporates effect of uncertainty, physical, monetary, and personal restraints, and other parameters and variables), some time would be required to determine the share necessary to restrain supply to levels resulting in goals of price and income improvement.

We do not propose that this policy instru-

[5] The function of total output $(1.25S_1$ including the government share, since S_1 represents only the .8 portion marketed by farmers) is identical with the function S_2 (which denotes total output under the situation).

ment outlined is one of political acceptability to all farm groups. However, the proposition is one of logical consistency and, it is hoped, adds to the intellectual environment surrounding farm policy analyses.

Because of its theoretical nature and limitations on space, we have not pursued various other ramifications of the particular program. It is perhaps likely that even under its income improvement the mechanism would be more effective than traditional land retirement in preventing a further overcommitment of resources in agriculture over the long run. This tendency might be restrained through a higher rental rate of tax in kind for new entrants in farming. Programs of the past decade have brought much greater gains to large, high income farms than to those at the other end of the scale. A differential set of rental shares among farmers could be used to benefit all farmers, but to bring a relatively larger gain to those of low-income strata. It is possible that a program of this type would have a somewhat greater social cost in underemployment of resources than existing voluntary land retirement programs (where farmers with low comparative advantage participate and those with high advantage remain out). However, it is unlikely that social costs in this context would be greater than for a program of compulsory marketing quotas where a restraint is placed on all farmers irrespective of their efficiency and comparative advantage.

This article concerns itself with the technical aspects of a policy mechanism. Other analyses can examine the long-run, social cost, and distributive characteristics of its potential variants. A policy in the general framework then might be outlined to have acceptance to farmers, improve equity, lessen competition for treasury outlays, and attain other relevant goals.

Stochastic Programming, Utility, and Sequential Decision Problems in Farm Management*

Allan N. Rae

This paper presents a further development of discrete stochastic programming, viewed within the context of Bayesian decision theory. Some probability models and information structures (with and without additional information) are discussed, followed by an indication of how the stochastic programming matrix may be set up to reflect the various information structures. Some expected utility theories are then reviewed, and their usefulness in allowing the specification of a wide variety of objective functions for the stochastic programming model is illustrated. Lastly, a method is presented for determining the money value of additional information, additional resources, and the expected cost of uncertainty.

Farm management typically requires that decisions be made at times when the outcomes or implications of those decisions will not be known with certainty by the farmer. Hence, many problems in farm management can be conveniently stated in terms of decision theory as they involve the specification of possible actions, states of nature, the probabilities of the states of nature, consequences of the actions given the various states of nature, and a utility function to be maximized.[1] The farmer might also have access to some additional information, such as weather or price forecasts.

Many farm management problems differ from the "conventional" specification of decision-theoretic problems in that the predefinition of all possible acts may be impossible; for example, the number of acts may be infinitely large, or acts may have to be chosen from within the confines of a restraint set. As such problems map readily into a mathematical programming framework, however, this paper will further develop a recently presented stochastic programming model [6] so as to make the method applicable to a wider range of decision problems encountered in farm management research.

Probability Models

The actual outcome of the decision-maker's action in a stochastic decision problem will depend upon the choice, made by "nature," of an event (state of nature) from the complete set of such events. It will be convenient to think of nature's choice as being the outcome of a random experiment. In a sequential decision problem there will exist a whole series of actions, each followed by the performance of such a random experiment. Hence, let R be a probability model that represents the t-stage random experiment mathematically. R will be considered to be built up from, or decomposable into, separate random experiments

$$R_{n_t t}, \qquad t = 1, \cdots, T$$
$$n_t = 1, \cdots, N_t$$

where n_t (the number of possible experiments within each stage) may vary with t, and the random experiment to be performed at any stage may depend upon the outcomes of random experiments performed in previous stages. Let the mathematical models of $R_{n_t t}$ have the event sets

$$(1) \qquad \xi_{n_t t} = \{e_{j,n_t t}; j = 1, \cdots, s\}.$$

The subjective probabilities[2] of the simple events of $\xi_{n_t t}$ will be given by the set

$$(2) \qquad P_{n_t t} = \{p_{j,n_t t}; j = 1, \cdots, s\}.$$

It is possible that the actual values of the probabilities may change from one model to another, or with n_t.[3] Also, no restriction is implied by assuming that all the experiments $R_{n_t t}$ have the same (sufficiently large) number, s, of outcomes, since if the kth event, e_k, is impossible in some $R_{n_t t}$ its probability is zero, or $p_{k,n_t t} = 0$.

* The author wishes to acknowledge the helpful comments of K. D. Cocks, J. L. Dillon, and W. F. Musgrave on an earlier draft of this paper.

[1] See [4, 12, 16, 19] for expositions of modern decision theory.

[2] Since the model is intended to maximize the expected utility of the decision-maker, the probabilities of the simple events must also be those of the decision-maker, which indicate his relative strength of belief as to the outcome of nature.

[3] In other words, the probabilities may be conditional on the outcome of the random experiments of previous stages.

Allan N. Rae *is senior research officer in agricultural economics at Massey University, New Zealand.*

Hence a mathematical model R can be constructed to provide a representation of the random experiment by forming the direct product of all probability models $R_{n_t t}$. Thus the mutually exclusive and collectively exhaustive set of all possible outcomes of R will be derived[4] (along with their associated probabilities of occurrence) and will be indexed by r, $r = 1, \cdots, k$.

In some farm management problems there may exist the possibility that the decision-maker will obtain additional information about nature's likely choice from $\xi_{n_t t}$ before making a decision. A modified probability model is presented below in which it is assumed that forecasting experiments may be performed prior to nature revealing the outcome of the random experiments.[5] Let W be a probability model which forms a mathematical representation of the t-stage forecasting experiment. W, as was R, will be considered to be built up from separate forecasting experiments represented mathematically by

$$W_{m_t t}, \qquad t = 1, \cdots, T$$
$$m_t = 1, \cdots, M_t.$$

Let the models $W_{m_t t}$ have the event sets

$$(3) \qquad F_{m_t t} = \{f_{k, m_t t};\ k = 1, \cdots, s\}$$

where each forecast event implies a particular probability distribution of the states of nature. Since there exist a total of s possible outcomes of nature in any probability model $R_{n_t t}$, it will be assumed that any of these outcomes could be predicted by the forecasting experiment. The number of possible events in $F_{m_t t}$ will therefore also equal s.

Now, given the (prior) probabilities of the simple events in $\xi_{n_t t}$ and the probabilities of the forecasts conditional on the simple events, Bayes' theorem may be applied to derive the posterior probabilities of the simple events conditional on the forecasts

$$(4) \qquad P'_{n_t t} = \{p'_{j, n_t t};\ j = 1, \cdots, s\}$$

and the unconditional probabilities of the forecasts

$$(5) \qquad Q_{m_t t} = \{q_{k, m_t t};\ k = 1, \cdots, s\}.$$

Thus the mathematical model of the now Bayesian probability model will be given by the direct product $R' \times W$, $R'W$.

Information Structures and Matrix Construction

Decision problems may be characterized by their information structures, that is, the pattern of information receipts in relation to the decision dates. Several information structures can be handled by the stochastic programming model, and the design of the matrix for different structures is the main topic of this section.

Possible information structures may be classified as follows: At the beginning of stage t of the decision process, the outcomes of stages $t-i$, $t-i-1$, $\cdots$, are known with certainty by the decision-maker but the outcomes of stages $t-i+1$, $t-i+2$, $\cdots$, are known only in the form of probability distributions of outcomes conditional on the known outcomes of past time periods. Hence, if $i=0$, the decision-maker has complete knowledge of past and present; if $i=1$, he has complete knowledge of the past; and if $i>1$, he has incomplete knowledge of the past. As an example of the last structure, should $i=2$ the actual outcome of stage $t-2$ but *not* $t-1$ is known at the beginning of the tth stage. Thus the receipt of information is lagged by one time period.

The above information structures may be augmented where the decision-maker can receive a forecast (or perform some other experiment) to provide additional information on the actual outcome of nature in past stages or the likely outcome of nature in present and/or future stages.

Matrix construction in the case where $i=0$ has been discussed elsewhere [6], so attention here will be on the two information structures given when $i=1$, and when $i=1$ and a forecast of stage $t-i$, where $i=0$, is available to the decision-maker. Matrix construction for all other possible information structures should be clear after study of these examples. Concern will be mainly with the restraints $Ax \leq b$; the last restraint group in each example will simply

[4] Since no mention of possible acts is made in the probability model, the event probabilities are taken to be independent of the acts. Where this assumption is unacceptable, it may be possible to formulate the programming problem so that its solution would comprise several "runs," each run allowing only a certain subset of acts and hence the appropriate event probabilities.

[5] Here, interest lies mainly in preposterior analyses, in which the value of the experiments can be determined *before* they are undertaken. Thus the decision-maker has the opportunity to determine whether or not it will be profitable for him to undertake such experimentation or which of a number of alternative experiments is the most profitable.

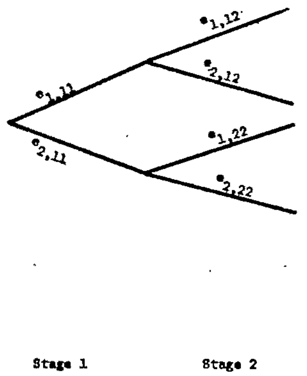

Figure 1. A two-stage probability model

collect net payoffs for each possible state of nature, which will then transfer the value to some appropriate objective function.[6] Although each information structure is treated separately, combinations of the various structures can be built into the matrix and may be encountered in practical sequential decision problems.

Complete knowledge of the past

The two-stage probability model of Figure 1 will be used to illustrate the case. The linear programming matrix would be constructed as in (6). Thus the vectors of activity levels x_{11}, x_{12} and x_{22} form a strategy. At the beginning of stage one the (permanently feasible) vector x_{11} is initiated. At the beginning of the second stage the decision rule would be: "Follow x_{12} if $e_{1,11}$ occurred in stage one, but follow x_{22} if $e_{2,11}$ occurred in the first stage."

(6) $\qquad$ maximize $E(u) = f\{w\}$

subject to

$$
\begin{array}{lllll}
A_{1,11}x_{11} & & & & \le b_{1,11} \\
 & A_{1,12}x_{12} & & & \le b_{1,12} \\
 & A_{2,12}x_{12} & & & \le b_{2,12} \\
A_{2,11}x_{11} & & & & \le b_{2,11} \\
 & & A_{1,22}x_{22} & & \le b_{1,22} \\
 & & A_{2,22}x_{22} & & \le b_{2,22} \\
-Ix_{11}^* & Ix_{12}^* & & & \le 0 \\
-Ix_{11}^* & & Ix_{22}^* & & \le 0 \\
-C_{11}x_{11} & -C_{12}x_{12} & -C_{22}x_{22} & +\{w\} & = 0
\end{array}
$$

[6] The manner in which such payoff values may be converted into an appropriate utility measure will be discussed in later sections.

where $E(u)$ is expected utility;

$A_{1,11}x_{11} \le b_{1,11}$ and $A_{2,11}x_{11} \le b_{2,11}$ are the restraints should event $e_{1,11}$ or $e_{2,11}$, respectively, occur in the first stage;

$A_{1,12}x_{12} \le b_{1,12}$ and $A_{2,12}x_{12} \le b_{2,12}$ are the restraints should event $e_{1,12}$ or $e_{2,12}$, respectively, occur in the second stage;

$A_{1,22}x_{22} \le b_{1,22}$ and $A_{2,22}x_{22} \le b_{2,22}$ are the restraints should event $e_{1,22}$ or $e_{2,22}$, respectively, occur in the second stage;

$\{w\}$ is some set of activities that transforms payoffs into the appropriate utility levels;

x_{11}^* is a vector that includes only those activities that are continued into the second stage—likewise x_{12}^* and x_{22}^* include only those second-stage activities that were initiated in the previous stage; and

C is a matrix of payoff coefficients due to the activities x, where each row of the matrix contains the payoffs given each outcome of R.

Forecasts as additional information

This example will serve to illustrate matrix construction for those problems in which a forecast is available to the decision-maker. For this particular model the decision-maker, at the beginning of stage t, knows the outcomes of all previous stages and in addition receives a forecast that provides additional information on the likely outcome of stage t.[7] This situation will be illustrated with the two-stage probability model[8] of Figure 2. At the beginning of stage one either forecast $f_{1,11}$ or $f_{2,11}$ might be received. Unless the forecasts are perfect, either may be followed by one of two outcomes. For

[7] In this particular model a forecast of the outcome of stage t is received at the beginning of stage t (for example, a forecast of weather to be experienced during stage t). Other possibilities exist, though, such as successively more accurate forecasts of the outcome of stage $t+k$ being received at the beginning of stages $t, t+1, \cdots, t+k$ (for example, forecasts of crop prices received throughout the growing season). Computation of probabilities through Bayes' theorem would then be a sequential process, with the posterior probabilities of one random experiment becoming the prior probabilities of the next.

[8] All probabilities in this model would be calculated by application of Bayes' theorem. For example, $q_{1,11}$ and $q_{2,11}$ would be the unconditional probabilities of the forecast events $f_{1,11}$ and $f_{2,11}$ respectively, and $p_1'{}_{,11}$ and $p_2'{}_{,11}$ would be the posterior probabilities of events $e_{1,11}$ and $e_{2,11}$ respectively, conditional on the receipt of $f_{1,11}$.

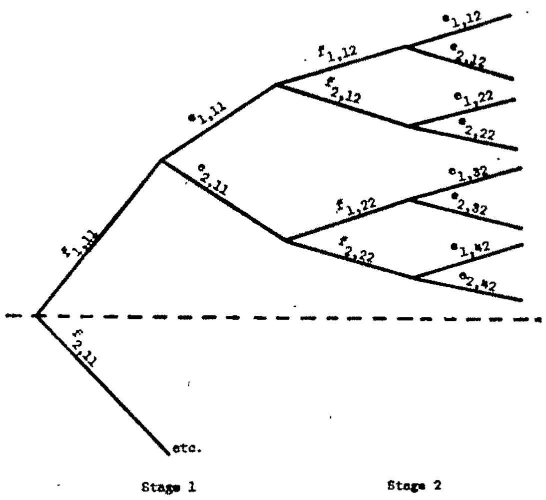

Figure 2. A two-stage probability model with additional information

example, following the receipt of $f_{1,11}$ the decision-maker (at the *end* of stage one) may have observed either $e_{1,11}$ or $e_{2,11}$. Since the stage one decision rule will consist of two actions, one for each possible forecast, the decision problem may be decomposed into two separate stochastic programming problems. One will assume that forecast $f_{1,11}$ is received, and the other will assume the receipt of $f_{2,11}$. The matrix structure of the first subproblem is illustrated in (7).[9]

where $A_{2,11}$ and $b_{2,11}$, for example, is the matrix of activity resource requirements and the vector of resource supplies, respectively, appropriate to the event $e_{2,11}$.

The activity vectors $x_{k,m_t t}$ may be interpreted as follows: "If the forecast event $f_{k,m_t t}$ is received, then operate activities at the levels indicated by the vector $x_{k,m_t t}$." For example, if forecast $f_{1,11}$ was received at the beginning of stage one, activities would be initiated at the levels given by $x_{1,11}$.

Utility Models

The solution of stochastic programming problems requires that the decision-maker can express preferences between probability distributions of outcomes or, the same thing, between strategies that give rise to the probability distributions. Various theories of utility have been proposed as models of rational behavior, and each consists of a number of axioms of "rational behavior" which, if satisfied by the decision-maker, would guarantee the existence of a

[9] If the expected utility of each optimal strategy (from the two subproblems) is $E(u_1^*)$ and $E(u_2^*)$, then the expected utility of the Bayesian strategy will be given by $E(\bar{u})$, where

$$E(\bar{u}) = q_{1,11}E(u_1^*) + q_{2,11}E(u_2^*).$$

$$\text{(7)} \qquad \text{maximize } E(u_1) = f\{w_1\}$$

subject to

$$\begin{array}{cccccccc}
A_{1,11}x_{1,11} & & & & & & \le & b_{1,11} \\
 & A_{1,12}x_{1,12} & & & & & \le & b_{1,12} \\
 & A_{2,12}x_{1,12} & & & & & \le & b_{2,12} \\
 & & A_{1,22}x_{2,12} & & & & \le & b_{1,22} \\
 & & A_{2,22}x_{2,12} & & & & \le & b_{2,22} \\
A_{2,11}x_{1,11} & & & & & & \le & b_{2,11} \\
 & & & A_{1,32}x_{1,22} & & & \le & b_{1,32} \\
 & & & A_{2,32}x_{1,22} & & & \le & b_{2,32} \\
 & & & & A_{1,42}x_{2,22} & & \le & b_{1,42} \\
 & & & & A_{2,42}x_{2,22} & & \le & b_{2,42} \\
-Ix^*_{1,11} & Ix^*_{1,12} & & & & & \le & 0 \\
-Ix^*_{1,11} & & Ix^*_{2,12} & & & & \le & 0 \\
-Ix^*_{1,11} & & & Ix^*_{1,22} & & & \le & 0 \\
-Ix^*_{1,11} & & & & Ix^*_{2,22} & & \le & 0 \\
-C_{1,11}x_{1,11} & -C_{1,12}x_{1,12} & -C_{2,12}x_{2,12} & -C_{1,22}x_{1,22} & -C_{2,22}x_{2,22} & +\{w_1\} & = & 0
\end{array}$$

utility function for that individual.[10] In stochastic programming the strategies will possess probability distributions of one-dimensional or multidimensional outcomes, and expected utility theory will be found useful in expressing preferences between such strategies and allowing the decision-maker's preferences to be transformed into a numerical function which may then serve as the objective function of the stochastic programming model.[11]

The problem of utility measurement over time can be approached in either one of two ways. First, the additive utility approach requires the specification of future utility functions u_t, $t=1, \cdots, T$, and the aggregate utility value of any stream of payoffs is computed as the sum of (discounted) utility values received in each future time period [25]. Second, the components of the payoff stream may be discounted and summed to a present value and *then* converted to a utility value [22].

The second approach is adopted here since only one utility function is required to be estimated, that which relates utility to payoff present values. The first approach is perfectly compatible with the stochastic programming model but is believed to be difficult to implement in practice because of the necessity of having to estimate future utility functions.[12]

The discount factor used in the calculation of present values should be that specified by the decision-maker so as to express his personal preference, or "impatience," for present over future returns. "Eventual" impatience may be handled by discounting only for periods sufficiently far away in the future, so discounting may not occur in the near future [8]. Of course, if the decision-maker has no time preferences or if the planning period is of a sufficiently short duration, the future will neither be discounted nor "overcounted" with respect to the present. Lexicographic utilities could be useful where decision-makers are overwhelmingly concerned with immediate returns or where the nature of the "flow" of returns over the planning period is of importance.

The one-dimensional expected utility model

Expected utility theory implies that a number (or utility) can be assigned to each of the r, $r=1, \cdots, k$, possible outcomes of a strategy, and that the expected utility of a strategy can be computed as a weighted sum of such utilities, the weights being probabilities $p^{(r)}$, $r=1, \cdots, k$. Bernoulli [2] and, later, von Neumann and Morgenstern [37] were the first to state axioms of ordering, independence, and continuity (or the Archimedean axiom) which implied the expected utility theorem. Since then different authors have developed different sets of axioms which are roughly equivalent.[13]

As guidelines of rational behavior, some of these axioms have been subject to criticism, and modified sets of axioms have been proposed as more suitable for certain preference structures. Some of these alternative models, such as lexicographic utilities, will be referred to later.

A general formulation of the one-dimensional objective function.—The approach adopted to incorporate the decision-maker's utility function into the programming model is to approximate the function with a number of linear segments. A utility function that is convex from above implies strict risk aversion on the part of the decision-maker, and by approximating such a function with a number of linear segments the convexity assumption of linear programming holds good. Should the utility function be nonconvex, it may still be approximated with a number of linear segments and incorporated into a linear programming model, provided that the analyst has access to a linear programming algorithm that contains a separable programming subroutine [18, ch. 4]. This technique, however, is recommended only for "slightly concave" separable functions; if the utility function is "highly concave," the decision-maker should be willing to settle for a local rather than a global optimal solution.

The objective function of the stochastic linear (or separable) programming problem may be set up as in (8). In this example, monetary payoffs are discounted and summed to a present value before being converted to a utility measure.

$$\text{(8)} \qquad \text{maximize } E(u) = p'u$$

subject to

$$[-c_t^{(r)}x_t + (1+\eta)^t w_{at}^{(r)} - (1+\eta)^t w_{bt}^{(r)} = 0; \quad r = 1, \cdots, k]; \qquad t = 1, \cdots, T$$

$$-\sum_{t=1}^{T} w_{at}^{(r)} + \sum_{t=1}^{T} w_{bt}^{(r)} + w^{(r)}I \leq 0;$$

[10] For reviews of utility theory, see [9, 14].

[11] The following expected utility theories are taken from [14, pp. 354–360].

[12] Not even at the University of New England have we been successful in estimating farmers' *future* utility functions!

[13] See, for example, [4, ch. 4; 26, ch. 2].

$$r = 1, \cdots, k$$
$$-\delta' w^{(r)} + u^{(r)} \leq 0$$
$$x_t, w_{at}, w_{bt}, w^{(r)}, u \geq 0$$
$$w_{at} \cdot w_{bt} = 0;$$
$$t = 1, \cdots, T$$

where

$E(u)$ is expected utility;

p is a vector of probabilities $p^{(r)}$, $r = 1, \cdots, k$;

u is a vector of utilities $u^{(r)}$, $r = 1, \cdots, k$;

x_t is a vector of activities which could be operated in stage t of the decision process, $t = 1, \cdots, T$;

$c_t^{(r)}$ is a vector of payoff coefficients given the occurrence of the rth nature state in the tth stage;

η is the decision-maker's time preference discount rate;

w_{at} is a vector of positive payoffs $w_{at}^{(r)}$, $r = 1, \cdots, k$, of the tth stage;

w_{bt} is a vector of negative payoffs $w_{bt}^{(r)}$, $r = 1, \cdots, k$, of the tth stage; and

$w^{(r)}$ is a vector of intermediate activities which transforms the payoff present value given the rth nature state to a utility value by means of the vector of coefficients δ.

The final (nonlinear) restraint in (8) is redundant, since it will be automatically satisfied by the normal linear (or separable) programming algorithm.

Expected loss as a measure of risk.—Loss can be defined as $\min(C, 0)$ where C is the net payoff, given some state of nature. Thus when $C \geq 0$,

$$\text{(9)} \quad \begin{aligned} \text{loss} &= -\min(C, 0) = 0, \quad \text{but when } C < 0 \\ \text{loss} &= -\min(-C, 0) = C. \end{aligned}$$

If the decision-maker maximizes the expected value of some utility function and chooses among alternatives solely on the basis of expected return and expected loss, the expected utility function will be of the form

$$\text{(10a)} \quad E(u) = aE(C) - bE[-\min(C, 0)]$$

where a and b are constants.

An objective function of the stochastic programming model corresponding to the utility function of (10a) could be set up as in (11). Here, as in all later examples, a zero discount rate is assumed. Should discounting be necessary, however, the formulation of the previous objective function should indicate the required modifications to the examples.

$$\text{(11)} \quad \text{maximize} \quad E(u) = p'w_a - \phi p'w_b$$

subject to

$$-\sum_{t=1}^{T} c_t^{(r)} x_t + w_a^{(r)} - w_b^{(r)} = 0;$$
$$r = 1, \cdots, k$$
$$x_t, w_a, w_b \geq 0$$
$$w_a \cdot w_b = 0$$

where

ϕ is a "risk-aversion" parameter;

w_a is a vector of positive payoffs $w_a^{(r)}$, $r = 1, \cdots, k$;

w_b is a vector of negative payoffs $w_b^{(r)}$, $r = 1, \cdots, k$; and other variables and coefficients are as earlier defined.

The last (nonlinear) restraint in (11) will always be satisfied by linear programming, provided that $\phi \geq 1$.

By setting $\phi = 1$, the above objective function represents a *linear* utility function. Should $\phi = 2$, however, the objective may be written as in (12).

$$\text{(12)} \quad \begin{aligned} \text{maximize } E(u) &= p'w_a - 2p'w_b \\ &= p'(w_a - w_b) - p'w_b \\ &= E(\text{payoff}) - E(\text{loss}). \end{aligned}$$

Hence a comparison with the expected utility function of (10a) indicates that $\phi = 2$ implies $a = b = 1$. Assuming $a = 1$ always, the value of b (in the expected utility function) will always be one less than the value of ϕ in the programming objective. Obviously, a locus of all efficient expected payoff-expected loss pairs could be derived by parametrically varying ϕ.

The utility function based on expected payoff and expected loss could be modified by measuring loss below some payoff level d, rather than zero. Then, the right-hand-side value of zero in the first restraint of (11) would be replaced with the negative of d. An example of such an objective function will be illustrated in a later section, where d will be the satisficing level of some utility factor in a multidimensional function.

With a little matrix manipulation, it would be possible to minimize expected loss, where loss is measured below *expected payoff*, subject to expected payoff being at least as great as some predefined value which could be varied parametrically. This would give rise to the

"linear-counterpart" of an expected payoff-semivariance frontier.[14]

In an earlier section it was noted that neither approach to utility maximization over time took account of the *pattern* of receipts over time. Now, should the nature of the "flow" of receipts be of importance to the decision-maker, the expected loss objective function of (11) could be modified by introducing new rows to the matrix that would collect payoffs for each time period separately. Thus a different weighting, ϕ_t, could be assigned to expected loss in any time period t, $t=1, \cdots, T$. Should the decision-maker wish to avoid large losses over the initial stages of the planning period, the corresponding values of ϕ_t could be given a higher value than the ϕ_t appropriate to the later stages. Again, by varying the values of ϕ_t, $t=1, \cdots, T$, a whole series of solutions could be obtained. The distributions of payoff streams of each solution may then be isolated so as to guide the decision-maker in his final, subjective, choice of strategy.[15]

A note on stochastic quadratic programming and *E-V* analysis.—The discrete stochastic programming problem may be formulated as one of quadratic risk programming, since all variability in the programming coefficients is eventually reflected in the objective function [6, p. 75]. In this way the complete E-V boundary can be generated and the strategy that maximizes expected utility can be located.[16] The analysis need not be restricted to quadratic utility functions; utility functions of higher order than the second may be employed, provided that they are subject to a Taylor's series approximation so that expected utility is a function of only the mean and variance of the distribution of outcomes.

One advantage of the quadratic programming approach is that a complete E-V boundary would be generated, and if a subjective choice can be made amongst all efficient strategies the need for empirical estimation of the decision-maker's utility function will be obviated. A disadvantage, however, is that the stochastic programming model will generally be very large when specified as a linear program; the quadratic programming matrix would be approximately twice as large and computational problems might be encountered.

The multidimensional expected utility model

Should the decision-maker's preferences be influenced by a number of factors, multidimensional utility functions [11] will be required to characterize the relationship between the different factors. The utility derived by the decision-maker from the operation of a strategy might be a function of both net income and terminal assets, for example, rather than just net income alone. Now, should the decision-maker be able to specify trade-off relations between all arguments of the multidimensional utility function, indicating how much the utility of one factor must be increased to offset a decrease in the utility of another factor, then utility is effectively one-dimensional and the expected utility theorem and its axioms remain applicable on the addition of certain additivity and independence assumptions. If such trade-offs cannot be specified—for example, one factor may be overwhelmingly more important than another—then lexicographic utilities become appropriate.

Additive utilities and the independence assumption.—Let $\Gamma=\{\gamma_j\}$ be the set of all feasible solutions to the stochastic programming problem, where each is characterized by a probability distribution of outcomes defined on a set of consequences Π. In the multidimensional case, Π will be the Cartesian product $\Pi_1 \times \Pi_2 \times \cdots \times \Pi_n$ where Π_i, $i=1, \cdots, n$, is the set of all possible levels of the ith payoff factor. Also, Γ_i will be interpreted as the set of all probability distributions of the ith payoff

[14] It would also be possible to reformulate the objective so as to minimize the expected absolute deviation, again measured about expected payoff, where expected absolute deviation would be given by $[p'(w_a+w_b)]$. Thus the "linear counterpart" of an expected payoff-variance frontier could be derived.

[15] Utility functions based on either expected loss or expected absolute deviation consist of two linear segments, and Markowitz criticizes their use on the basis of these segments, especially that over the region $C \leq 0$ [28, pp. 287–297]. His argument is that choices are made among alternatives with negative payoffs on the basis of expected return only, and a resulting strategy might chance a substantial monetary loss when a more conservative strategy with a slightly lower expected return could have been chosen. Be that as it may, these functions are felt to be an improvement over some commonly used; for example, they provide a better approximation to a risk-averse utility function than do linear functions.

[16] Some controversy exists in the literature as to the usefulness of quadratic utility since such a function implies that risk aversion will increase rather than decrease with increasing wealth [30, 35]. This criticism is not seen to be relevant here, however, since the quadratic utility function refers to annual money gains and losses about some given wealth level [1, sections 4.2.1 and 4.2.2].

factor, so given any strategy γ_j in Γ, γ_{ij} in Γ_i may be identified as the marginal distribution of strategy γ_j on Π_i. Now, the theory of additive expected utility says that a utility can be attached to each γ_{ij} in Γ_i, $i=1, \cdots, n$, so that the expected utility of strategy γ_j can be computed as in (13).

$$u(\gamma_j) = \sum_{i=1}^{n} u_i(\gamma_{ij}). \tag{13}$$

That is, the expected utility of any strategy can be found by simply summing the expected utilities of each factor [12, ch. 9].

For condition (13) to be true, it has been shown that an independence axiom must be applicable in addition to those mentioned in relation to the one-dimensional expected utility model [14, pp. 358–359]. The effect of this assumption is to allow preferences to be formed among strategies on the basis of their marginal distributions. It is a simplifying assumption in that it rules out the possibility of *interaction* among factors and is analogous to an analysis of variance assumption that only first-order effects will be significant, thus ruling out possible cross-effects between factors.[17]

Multidimensional objective functions.—Any of the one-dimensional utility functions may be used to measure the utility of the payoff factors i, $i=1, \cdots, n$. Only one example of a multidimensional objective function will be presented, in which each utility function u_i expresses a nonlinear relation between utility and the level of the ith factor. This objective function is illustrated in (14). Of course, the u_i functions may be either convex or nonconvex, and in practice one might perhaps find the u_i to contain linear, convex, and nonconvex functions. Also, if discounting of payoffs is considered necessary, the objective would be set up similarly to (8) except that time preference discount rates η_i, $i=1, \cdots, n$, would have to be estimated for each payoff factor.

$$\text{maximize } E(u) = \sum_{i=1}^{n} \alpha_i(p'u_i) \tag{14}$$

subject to

$$\begin{array}{llll}
-\sum_{t=1}^{T} c_{1t}^{(r)}x_t + w_1^{(r)}I & & & \leq 0; \\
& & & r=1, \cdots, k \\
& -\delta_1' w_1^{(r)} + u_1^{(r)} & & \leq 0 \\
\vdots & & \ddots & \vdots \\
-\sum_{t=1}^{T} c_{nt}^{(r)}x_t & & + w_n^{(r)}I & \leq 0 \\
& & -\delta_n' w_n^{(r)} + u_n^{(r)} & \leq 0 \\
& & x_t, w_i^{(r)}, \quad u_i & \geq 0
\end{array}$$

where

- α_i, $i=1, \cdots, n$, are weights representing the trade-off between factors;[18]
- u_i, $i=1, \cdots, n$, are vectors of utility values $u_i^{(r)}$, $r=1, \cdots, k$;
- $c_{it}^{(r)}$, $r=1, \cdots, k$, are vectors of payoff coefficients of the ith factor, $i=1, \cdots, n$ in the tth time period, $t=1, \cdots, T$;
- $w_i^{(r)}$, $r=1, \cdots, k$, are vectors of intermediate activities which transform the payoff distribution of the ith factor, $i=1, \cdots, n$, to a utility distribution u_i, $i = 1, \cdots, n$, by means of the vectors of coefficients δ_i, and other variables and coefficients may be interpreted as before.

---

[17] Where the independence assumption is unsatisfactory, it may be possible to specify the function in quadratic form as

$$u(\gamma_j) = \sum_{i=1}^{n} u_i(\gamma_{ij}) + \phi_{ik} \sum_{i=1}^{n} \sum_{k=1}^{n} u_i(\gamma_{ij})u_k(\gamma_{kj})$$

where $i=k$ is permissible. Thus the stochastic linear programming model would be converted to one of quadratic programming. For a method of estimating such "quasi-separable" utility functions, see [24].

[18] Although much has been written about the problem of determining weighting coefficients in multidimensional utility functions [10, 13], the view taken here is that there is no real need for an a priori determination of the weights. Instead, the versatility of parametric programming may be utilized to obtain solutions for a whole series of weight combinations. Then by allowing the decision-maker to make a subjective choice among solutions, the true weights will be revealed. A sensible routine would probably involve the specification of a fairly coarse "grid" of possible weight combinations at first; the decision-maker's preferences among the strategies so obtained could give some indication of the true weights, so that successively finer grids could then be located and employed. In this way, the solutions would gradually reveal the decision-maker's subjective system of factor weights.

Multidimensional functions and satisficing behavior.—The multidimensional utility function is also applicable where decision-makers exhibit satisficing rather than optimizing behavior [7]. The decision-maker in this case might express preferences among strategies in accord with "how near," in some sense, the factor levels given by the strategies come to prespecified levels of the factors. Such an objective function can be constructed by specifying the utility functions u_i according to the expected loss criteria; that is,

$$u_i = a_iC_i - b_i[-\min(C_i - d_i, 0)], \quad i = 1, \cdots, n \tag{10b}$$

where

$a_i=0$ and d_i is the satisficing level of the ith factor, $i=1, \cdots, n$.

The objective function of the stochastic programming problem could be set up to minimize the sum of the expected values of the appropriately weighted deviations below the satisficing levels of the factors,[19] as in (15).

$$\text{maximize } E(u) = -\sum_{i=1}^{n} \alpha_i(p'w_{ib}) \tag{15}$$

subject to

$$\begin{array}{llll}
-\sum_{t=1}^{T} c_{1t}^{(r)}x_t + w_{1a}^{(r)} - w_{1b}^{(r)} & & = -d_1^{(r)}; & r = 1, \cdots, k \\
-\sum_{t=1}^{T} c_{2t}^{(r)}x_t & + w_{2a}^{(r)} - w_{2b}^{(r)} & = -d_2^{(r)} & \\
\vdots & \ddots & \vdots & \\
-\sum_{t=1}^{T} c_{nt}^{(r)}x_t & \quad + w_{na}^{(r)} - w_{nb}^{(r)} & = -d_n^{(r)} & \\
 & x_t, w_{ia}, w_{ib} \geq 0 & & \\
 & w_{ia} \cdot w_{ib} = 0; & & i = 1, \cdots, n
\end{array}$$

where

d_i is the satisficing level of the ith factor, $i=1, \cdots, n$;

w_{ia} is a vector of elements $w_{ia}^{(r)}$, $r=1, \cdots, k$, which measure the extent to which the ith factor is "oversupplied" in the rth environment;

w_{ib} is a vector of elements $w_{ib}^{(r)}$, $r=1, \cdots, k$, which measure the extent to which the ith factor is "under-supplied" in the rth environment; and all other variables and coefficients are as previously defined.

The lexicographic expected utility model

The Archimedean axiom limits utility spaces to one dimension, or the real numbers. While this axiom is acceptable to decision-makers with only a single goal, or to those with multiple goals who have established acceptable trade-off relations between them, it will be unacceptable in situations where substitution of achievement between goals is not possible. To cover such possibilities, the theory of utility has been generalized by either weakening or omitting the Archimedean assumption [5, 21, 32]. Preferences are not then ranked according to single-valued expected utilities, but rather according to lexicographically ordered *vectors* of expected utility values.

The lexicographic expected utility theory [14, pp. 349–350 and 358] states that a utility $u_i(\gamma_{ij})$ can be attached to each γ_{ij} in Γ_i, $i=1, \cdots, n$, so that if γ_1 and γ_2 are two strategies in Γ with marginal distributions γ_{i1} and γ_{i2} respectively on the Π_i, $i=1, \cdots, n$, then γ_1 will not be preferred to γ_2 if and only if condition (16) is true.

$$[u_1(\gamma_{11}), u_2(\gamma_{21}), \cdots, u_n(\gamma_{n1})] \overset{L}{\leq} [u_1(\gamma_{12}), u_2(\gamma_{22}), \cdots, u_n(\gamma_{n2})]. \tag{16}$$

[19] This multidimensional objective function may be thought of as a stochastic formulation of the goal programming models first described by Charnes and Cooper [3, pp. 215–221] and developed by Ijiri [23, chs. 2–4]. It should perhaps be mentioned that the specification of some goals might involve the minimization of the deviation *above* the goal (e.g., the amount of labor hired).

The lexicographic order $\overset{L}{\leq}$ may be interpreted as meaning that γ_1 will not be preferred to γ_2 if and only if $u_1(\gamma_{11}) < u_1(\gamma_{12})$, or $u_1(\gamma_{11}) = u_1(\gamma_{12})$ and $u_2(\gamma_{21}) < u_2(\gamma_{22})$, or $\cdots$ or $u_i(\gamma_{i1}) = u_i(\gamma_{i2})$ for all $i < n$ and $u_n(\gamma_{n1}) \leq u_n(\gamma_{n2})$.

Lexicographic objective functions.—All the comments on multidimensional objective functions remain applicable to lexicographic functions with the one exception that the trade-off weights α_i are not measurable. Given the i factors and their utility functions u_i, $i = 1, \cdots, n$, the lexicographic objective could be set up as in (14), for example, but only utility values for the first factor would have a positive valuation in the objective.[20] Having maximized the expected utility of the first factor, the solution should be examined for alternative optimal solutions.[21] If none exists, the solution obtained will be optimal in terms of the lexicographic ordering (16). If alternative optimal solutions are found to exist, the value of expected utility for all other factors, that is, $u_2(\gamma_{2j}{}^*)$, $u_3(\gamma_{3j}{}^*)$, $\cdots$, etc., would need to be computed from each alternative optimal solution (where the asterisk superscript denotes that the jth strategy is an alternative optimal strategy). Then all expected utilities may be ranked as

$$[u_1(\gamma_{1j}{}^*),\ u_2(\gamma_{2j}{}^*),\ \cdots,\ \text{etc.}]$$

for each alternative solution and the truly optimal solution could be located according to condition (16).

Lexicographic functions and satisficing behavior.—To represent satisficing behavior on the part of the decision-maker, the lexicographic utility function could include not only a ranking of the payoff factors but also the satisficing levels of the factors, d_i, $i = 1, \cdots, n$. The stochastic programming objective would then be to maximize the expected utility of the *least* important factor, subject to the attainment of at least the satisficing expected utility values of all other factors.[22] The stochastic programming objective, in this example to guarantee that the expected level of the ith factor is at least as great as the satisficing level d_i, could be set up as in (17).

(17) $$\text{maximize } E(u) = p'(w_{na} - w_{nb})$$

subject to

$$\begin{aligned}
-\sum_{t=1}^{T} \overset{(r)}{c}_{1t} x_t + \overset{(r)}{w}_{1a} - \overset{(r)}{w}_{1b} &= 0; \qquad r = 1, \cdots, k \\
p'w_{1a} - p'w_{1b} &\geq d_1 \\
\vdots \qquad\qquad &\qquad \vdots \\
-\sum_{t=1}^{T} \overset{(r)}{c}_{n-1,t} x_t + \overset{(r)}{w}_{n-1,a} - \overset{(r)}{w}_{n-1,b} &= 0 \\
p'w_{n-1,a} - p'w_{n-1,b} &\geq d_{n-1} \\
-\sum_{t=1}^{T} \overset{(r)}{c}_{nt} x_t + \overset{(r)}{w}_{na} - \overset{(r)}{w}_{nb} &= 0 \\
x_t,\ w_{ia},\ w_{ib} &\geq 0 \\
w_{ia} \cdot w_{ib} &= 0; \qquad i = 1, \cdots, n
\end{aligned}$$

where all variables and coefficients are as previously defined. If no feasible solution to (17) existed, the nth factor would be dropped from the objective and the expected utility value of the attainment of the $(n-1)$th factor would be maximized subject to the attainment of the satisficing levels of expected utility for all

[20] That is, $\alpha_1 > 0$ and $\alpha_i = 0$ for $i = 2, \cdots, n$.

[21] Alternative optima will exist if at least one nonbasic vector has a zero shadow price and if that vector can be included in the basis at a positive level (hence the alternative optima cannot simply be alternative degenerate optimal solutions); see [17, pp. 166–168].

[22] Halter and Dean have illustrated this approach, although only with a nonstochastic example; see [19, pp. 67–69].

other factors i, $i=1, \cdots, n-2$. This process would be continued until the first feasible solution was obtained.

The above objective function could be rewritten as multidimensional in *time* rather than in the number of payoff factors. For example, expected utility could be maximized subject to the requirement that expected utility of *each time period* was at least as great as a predefined satisficing level. Hence this approach would be another way in which account could be taken of interperiod variability in payoffs.

The choice of a utility function

If the analyst is satisfied that for the decision-maker utility is a function of one variable only, say net income, then by appropriate questioning the utility function may be derived [27, 29]. A graph of points in utility-net income space could then be constructed, from which the analyst can derive an estimate of the utility function's shape. He can then decide which of the functions of the above sections give the best approximation to that function, bearing in mind that some functions (for example, linear functions) are the simplest and probably least expensive to use (in terms of required computer time), and still others (nonconvex separable functions) require access to a specialized computing algorithm and may result in the location of local, rather than global, optimal solutions.

Should the decision-maker's utility be multidimensional, a similar procedure would be followed to establish each of the functions u_i, $i=1, \cdots, n$.

It should be remembered that whether the chosen function provides a good approximation to the underlying utility function will not simply depend on how closely the function fits the graphed points but rather on the sensitivity of "optimal" strategies to changes in the shape of the utility function, in the true value of expected utility as a result of such changes, and in the costs of implementing the various functions.

The Value of Additional Information

It is often of interest to a decision-maker to know the extent to which expected utility might be increased through the acquisition of additional information, or perhaps to know what it would be worth if all uncertainty could be removed from the decision problem. Since the discrete stochastic programming model can accommodate various information structures, it can also indicate the value of moving from one structure to another and the maximum amount the decision-maker could afford to pay to obtain such additional information.[23]

Where utility is one-dimensional and a linear function of money income, such values are easily derived provided that the model includes no restraints on cash supplies. Then the value of some additional information may be measured by subtracting the expected net income of the original ("no-data") optimal strategy from the expected net income of the Bayesian strategy which incorporated the additional information. Thus the quantity derived is the maximum amount of money that the decision-maker could afford to pay to obtain the additional information.

The above ex post determination may not be correct where the model includes cash restraints, since payment for the information may give rise to infeasibilities under some eventuating nature states. Also, where utility is a nonlinear function of money or is multidimensional, the above analysis would involve a comparison between two expected utility values. In all these cases a monetary value can be given to the additional information by determining that sum of money which, if added to fixed costs of the time period when the information must be paid for, would give, on problem solution, a strategy with an expected utility identical with that of the no-data strategy.[24] In other words, knowing the expected utility of the no-data strategy, the Bayesian programming model would be re-solved several times, with a successively higher addition to fixed costs, until expected utility became equal to that of the no-data strategy.[25]

Once a stochastic programming problem has been solved, the expected cost of uncertainty can be calculated by reformulating and solving

---

[23] The approach adopted here to valuing additional information is an application of a method suggested by Harvey [20] and explained further in [19, pp. 132–138].

[24] Where utility is a function of several factors, fixed costs would only be entered in the rows of the matrix appropriate to the "cash" factor.

[25] This procedure will determine the *maximum* price that can be paid for the additional information. Of course, if the *actual* cost of the additional information is known prior to problem solution, this amount should correctly be added to fixed costs in the Bayesian problem. Then, provided that the expected utility of the Bayesian strategy exceeded that of the no-data strategy, acquisition of the extra information would be worthwhile.

the problem as one of passive stochastic programming.[26] Then all that is necessary is to determine that sum of money which the decision-maker could afford to pay for the perfect information and remain as well off, in terms of expected utility, as he would have been with the optimal strategy appropriate to the actual information structure.

Finally, the same procedure can be used to answer questions of factor acquisition under risk when the decision-maker's utility is a nonlinear function of money or multidimensional, or where the programming model includes cash restraints. For example, if a farmer had the opportunity to lease an additional 50 acres of land, two stochastic problems would be solved. The first of these would include the present land supply, and the second would include the additional land. Once an optimal strategy to the first problem had been obtained, the second problem would be solved several times with successively higher additions to fixed costs. When a strategy's expected utility became equal to that of the first (original) problem, the amount that had been added to fixed costs would represent the maximum price the farmer could afford to pay for the additional land.[27] It might also be of interest to compare this price with the increment in *expected income* that would result from purchase of the resource.

Summary and Implications

This paper has indicated how the sequential decision-theoretic problems often encountered in studies of farm and business management might be solved with the aid of discrete stochastic programming. The nature of this type of problem typically requires the allocation over time of limited supplies of resources among alternative production activities, where resource supplies, input-output coefficients, factor costs, and product prices may not be known with certainty at the various allocation dates.

It is believed that the usefulness of stochastic programming in solving such decision problems has been enhanced. Firstly, the paper has indicated how various information structures, particularly those involving forecasts, can be handled by the method; and secondly, it has demonstrated the manner in which a wide variety of expected utility functions can be specified as objective functions of the stochastic programming model.

The fact that such a wide variety of utility functions can be employed opens the door to many interesting studies such as the effect of decision-makers' preferences on resource allocation and valuation under risk within the firm. Thus it would be possible to test some theories (or formulate new ones) on optimal resource allocation under risk.[28]

Lastly, it has been shown that a money value may be imputed to additional information or increments to the firm's resource supplies. Thus the technique should be found useful in a wide range of Bayesian decision problems and in studies of factor acquisition under risk.

[26] Passive stochastic programming [34] assumes that the outcome of nature is known before any decisions must be made. It can thus be used to indicate the value of perfect knowledge of the future.

[27] It should be emphasized that once the *actual* cost of additional resources or information is known, the problem should be re-solved with the actual cost added to fixed costs to obtain the truly optimal strategy. The reason for this is the possibility of a change in optimal strategy occurring as the cost of extra resources or information is changed.

[28] This is a topic that has received considerable attention in the literature, since the traditional theory of the firm, which concentrated on optimal behavior under conditions of certainty, may not be satisfactory for situations involving risk. For example, [36] discusses the behavior of competitive firms; [15 and 38], the behavior of imperfectly competitive firms, under risk. In the latter case the stochastic programming model could approximate product demand and factor supply curves with step functions. Alternatively, by approximating the curves with linear functions, the decision problem would become one of quadratic programming, as demonstrated (for nonrisky situations) in [31].

Optimum Dairy Plant Location with Economies of Size and Market-Share Restrictions*

DONALD W. KLOTH AND LEO V. BLAKLEY

Significant economies are possible under optimum organizations of the U. S. dairy industry, but models that minimize industry costs with a single firm in each market overestimate the potential savings. The effects of market-share restrictions for processing firms are estimated. Costs are higher than under single-firm organizations but remain below levels for the current plant-size environment. The major interregional effect of the restrictions is on the regional identity of the firms processing milk for local markets, not on the total quantity of milk transported between regions. With market-share restrictions, more milk is processed locally.

LEAST-COST LOCATION of agricultural processing industries can be approached through relatively simple models. Many of the more interesting questions, however, require results from more complex models which utilize assumptions, market definitions, and market restraints that approximate more closely the actual market environment. The purpose of this article is to report the development of a fairly realistic model and its application to the dairy industry of the United States. It assesses the effects on total costs and interregional flows of milk under alternative degrees of market concentration when economies of size of processing plants (not requiring constant marginal processing costs) are permitted.

Three levels of market concentration are specified. "Model A" permits only a single firm in each market, and references to this model will be in terms of unrestricted plant sizes. "Model B" involves specific maximum relative sizes of plants for each market. Generally two or more plants serve each market, and references will be in terms of a restricted plant-size environment. "Model C" is an approximation of the existing plant-size environment but is estimated by a less sophisticated model using estimated average processing costs for each area.

The Model

The production-distribution model formulated by Martin [10] is used as the beginning point for Models A and B. Martin's model can be considered as an extension of the Stollsteimer model [11] and determines the optimum number, size, and location of processing plants that will minimize assembly, processing, and distribution costs. A similar model was used with restricted spatial monopoly by Bobst and Waananen [1].

Separable programming is one technique for extending Martin's model to permit consideration of the size economies. Crowder [5] used the separable programming technique in a production-distribution model designed for a study of a closed Oklahoma dairy economy. Crowder's basic model is employed in this study.

The model in equation form has the objective:

$$\text{(1)}\qquad \text{Minimize } TC = \sum_{j=1}^{n}\sum_{i=1}^{m} C_{ij}X_{ij} + \sum_{i=1}^{m} f(X_i) + \sum_{k=1}^{p}\sum_{i=1}^{m} T_{ki}X_{ki}$$

subject to the constraints:

$$\text{(2)}\qquad \sum_i X_{ij} = D_j$$

$$\text{(3)}\qquad \sum_i X_{ki} \le S_k$$

$$\text{(4)}\qquad \sum_k S_k \ge \sum_j D_j$$

$$\text{(5)}\qquad X_{ki} \text{ and } X_{ij} \ge 0$$

where

TC = total costs for the assembly, processing, and distribution of milk for fluid consumption;

X_{ij} = quantity of processed milk shipped from processing area i to demand area j;

C_{ij} = per unit distribution cost of shipping processed milk from processing area i to demand area j;

* Journal Article 2076 of the Oklahoma Agricultural Experiment Station.

DONALD W. KLOTH *is economist with the Corporate Planning Division of Anheuser-Busch, Inc.* LEO V. BLAKLEY *is professor of agricultural economics at Oklahoma State University.*

D_j = quantity of processed milk consumed in demand area j;

$f(X_i)$ = nonlinear function expressing the total cost of processing quantity X_i in processing area i;

X_{ki} = quantity of raw milk shipped from supply area k to processing area i;

T_{ki} = per unit assembly cost of shipping raw milk from supply area k to processing area i;

S_k = quantity of raw milk available in supply area k.

Economies of size in equation (1) are effective through $f(X_i)$, which is the representation of the nonlinear total cost curve for processing. The functional $f(X_i)$ can be used to approximate the cost curve to any degree of accuracy by substituting a number of linear transformations into a sum of functions of individual variables. If, for example, a function F can be written as

$$F = \sum_{i=1}^{m} f(X_i) \tag{6}$$

where

$$\sum_{i=1}^{m} f(X_i) = \sum_{i=1}^{m} \sum_{h=1}^{u} x_{ih}\theta_h, \tag{7}$$

x_{ih} is the hth variable of processing area i to enter the analysis, measured in terms of the quantity of milk in the hth interval, and

θ_h is the average processing cost associated with the quantity of milk in the hth interval,

then the function f (and, hence, F) can be approximated by piecewise linear functionals [3]. Separable nonlinear functions and the maximization of separable convex functions are discussed in more detail by Hadley [6, pp. 104–156]. The computer program employed is the IBM Linear and Separable Programming Routine [7, pp. 165–188].

Market share restrictions are imposed initially through maximum percentages of the local market permitted for individual firms. Specifically, the restriction is

$$X_{gij} < \alpha_{gj} D_j \tag{8}$$

where

X_{gij} = the quantity of milk processed by plant g in processing area i for demand area j, defined only for $i=j$,

α_{gj} = the maximum proportion of the market j served by plant g.

Ten relative plant sizes were specified for the analysis under Model A. A maximum of one plant was specified for any given market, but plant sizes were variable among markets. The selection of this plant (or importation of milk with no local plant) for a given market was from the smallest size of 7 percent of local consumption to the next to largest size of 10 million quarts per day, approximately the size when the minimum processing cost per quart is assumed to be reached (Table 1). A potential plant size larger than 10 million quarts per day (the special plant) was included as the largest size to give flexibility in the specifications for large markets or for exports to other markets. The 1965 producer Class I price structure was assumed for Model A.

Maximum plant sizes in the restricted market setting of Model B varied with the size of the market, the size sequence being reversed from that in Model A (Table 1). In the program the order of entry of plants is I, II, etc. For example, a second plant in a small market can enter the solution at a maximum capacity (or fraction of this maximum capacity) of 35 per-

Table 1. Maximum relative plant sizes specified for markets in models A and B

Plant number	Maximum plant size under: Model A		Model B	
	All size markets	Small-size markets[a]	Medium-size markets[b]	Large-size markets[c]
		percent of market sales		
I	7	55	55	55
II	15	35	30	25
III	35	10	10	10
IV	50	—[f]	5	7

VII	200			
VIII	250			
IX	—[d]			
Special plant	—[e]	50	50	50

[a] Markets with total sales of 75.0 million pounds per month or less.

[b] Markets with total sales of 75.1 to 150.0 million pounds per month.

[c] Markets with total sales in excess of 150.0 million pounds per month.

[d] Volume of 10 million quarts per day where the function approaches the assumed minimum cost of 1.8 cents per quart.

[e] Volume of up to 4.7 billion pounds per month, the total U. S. consumption.

[f] Blanks indicate not applicable, since no additional plant sizes in the market were permitted.

cent of the market sales only after the first plant is operating at the capacity specified by 55 percent of the market sales. The special plant can enter only when plants I, II, and III are operating. The primary function of the special plant is to provide for potential intermarket movements of packaged milk. The specifications are similar but with more potential plants and different share percentages for plants in the medium- and large-size markets. A base-point price structure based on 15 cents per hundredweight per 100 miles from Eau Claire, Wisconsin, is assumed for Model B.

A base for comparison is provided by the results from Model C, which uses estimated processing costs for existing numbers and sizes of firms in the industry. The 1965 producer Class I price structure was assumed. The models and the various restrictions employed are described in more detail by Kloth [9].

Data

Regions

The area of the study, which included the 48 contiguous states of the United States, was divided into 105 consuming markets and 92 areas of production. The delineation was based primarily on data furnished through correspondence with state agricultural agencies and federal order market administrators.

Production

Production of Grade A milk for the month of October 1965 was estimated for each county of the area. When county data were not available, estimates for markets or states were developed from class prices, average prices, average butterfat content, total milk production, and milk production not sold.

Consumption

Consumption was estimated for each market in order to have a uniform set of estimates for all markets. The building block for each demand area was the county. The estimated consumption for each market was the total population times the estimated per capita consumption for the market. The per capita consumption reflected the constant for the regional effect, the weighted average per capita income for the market and an assumed income elasticity of 0.16, the weighted average price in the market (from [12, pp. 36–39]) and an assumed price elasticity of −0.285, and a factor for the Caucasian population proportion in the market. The elasticity estimates are Brandow's [2, p. 17].

Costs

The assembly cost function relates to intermarket movement of unprocessed Grade A milk from production areas to processing areas. The cost function, based on Kerchner's [8] function for a 49,000-pound pay load is as follows:

$$T_{ki} = 11.405 + 0.1126M_{ki} \tag{9}$$

where

T_{ki} = assembly cost in cents per 100 pounds for transporting raw milk from a point in production area k to the point of processing in area i, and

M_{ki} = one-way mileage from production area k to processing area i.

The distribution cost relates to intermarket movement of processed Grade A milk from processing areas to demand areas. The cost function selected, also based on Kerchner's study, is as follows:

$$C_{ij} = 6.513 + 0.16025M_{ij} \tag{10}$$

where

C_{ij} = distribution costs in cents per 100 pounds for transporting packaged milk from processing area i to demand area j, and

M_{ij} = one-way mileage from processing area i to demand area j.

The processing cost function is one developed by Cobia and Babb [4]:

$$PC_{gi} = 11.763X_{gi}^{-0.11607} \tag{11}$$

subject to

$$PC_{gi} \geq K \tag{12}$$

where

PC_{gi} = processing cost in cents per quart for plant g in area i,

X_{gi} = quarts of milk processed per day by plant g in area i, and

K = 1.8 cents per quart, an assumed minimum.

Results of Plant-Size Restrictions

Firm numbers and sizes

An obvious expectation was that firm numbers would decrease and firm sizes increase from

Table 2. Distribution of Grade A fluid milk processing firms by size, region, and model fo the United States[a]

[a] Estimated numbers of firms for Model C: Western, 645; West South Central, 231; Southern, 587; North Central, 1524 and Northeastern, 562. It was estimated that approximately 90 percent of these firms had capacity of less than three millio pounds per month.

current levels under either Model A or Model B. The limit of reduction under efficient organization apparently would be indicated by the results from Model A, in which only 59 firms operated (Table 2). The largest facilities established for this model were in the Northeastern region—an average of 153 million pounds per month. This was followed by successively smaller average sizes in the North Central, Western, Southern, and West South Central regions in that order.

The imposition of plant-size restrictions in Model B resulted in about four times as many firms operating processing facilities as in Model A. The numbers of firms established at capacities of 50 million pounds or more per month were not greatly different in the two models except in the West South Central region. The greatest differences were in the numbers of smaller plants established, particularly plants with capacities of less than 10 million pounds per month. As a result, the average plant size was much smaller, 19.6 million pounds per month.

Cost comparisons

Total industry costs were not estimated. Omitted were (1) costs of assembly from the farm to the central location in the supply are and (2) costs of distribution from the potentia central processing location in each deman area through the retailing channels to the con sumers in that area. The latter costs tra ditionally are included in the distributor's cost at least those involved in transporting milk t retail stores and to homes via home delivery However, except for costs associated with du plication of services and differences in marke power, the omissions should affect only th share of total costs accounted for in the mode and should not appreciably affect the cost dif ferences among the models.

The costs of processing fluid milk in an in dustry with economies of plant size and wit excess plant capacity would be expected to de crease as the number of firms declined. The re sults were consistent with this expectation From $71.4 million for the current plant-siz environment (Model C), processing costs wer estimated to decline about one-third to $46. million when only a single firm operated in eac major market (Model A).

It is not necessary, however, to have only a single firm operating in each market to achiev significant reductions in processing costs. Unde the restricted plant sizes of Model B, processin

costs totaled only $54.2 million. In other words, two-thirds of the potential reduction in processing costs was achieved without limiting consumer choice to the product from only one firm in each market.

Fewer plant numbers are usually associated with fewer processing plant locations. This implies that both assembly costs for raw milk and distribution costs for packaged milk will increase as firm numbers decline. The implications will be valid, however, only if the comparative advantages among regions are unaffected by the changes in firm numbers.

Distribution costs followed the expected pattern and increased from $0.8 million for the current plant-size environment to $5.5 million for the single-firm organization. Over one-half the increase was associated with the change from the restricted plant size to the single-firm level of market concentration.

Assembly costs did not follow the expected pattern, although they were lower for the single-firm organization of the market than for the current plant-size environment. Assembly costs were highest for the restricted plant sizes (Model B) at $15.1 million, compared with $9.1 million for Model A, reflecting in part the impact of differential assumptions regarding price levels for milk. The price assumption for Model B was a basic Class I price in the upper Midwest plus a transfer cost to outlying points, while estimated 1965 Class I prices were used in Models A and C. The result was somewhat higher Class I prices in the more distant regions in Model B, which caused imports of raw milk from the Midwest to increase. The net effect was an increase in total assembly costs.

The total of processing, distribution, and assembly costs under the restricted plant-size environment was $71.8 million. Since total costs for Models A and C were $60.6 million and $83.8 million, respectively, the results indicate that only about one-half of the potential economies could be achieved in the restricted market setting, considerably less than the estimate of two-thirds based on processing costs considered alone.

Intermarket transfers

Model C provides a basis for estimating the minimum intermarket transfers of milk consistent with minimum costs for existing plants. The intermarket movements of raw and packaged milk totaled 2.1 billion pounds per month out of an estimated 4.7 billion pounds of final consumption. Only 4.8 percent of the intermarket transfers consisted of packaged milk, somewhat lower than the 7.3 percent reported for federal order markets in 1967.

Relaxing all market restrictions on firm numbers and sizes resulted in a substantial increase in intermarket transfers. The total for Model A was 3.1 billion pounds, an increase of one billion pounds over Model C. The increase was in intermarket transfers of processed milk, up to 26.7 percent of total processed milk.

In the restricted plant-size environment with more than one firm in each market (Model B), the results were intermediate between those in Model A and Model C. About 14.9 percent of total processed milk moved as packaged milk, approximately one-half the level indicated for Model A.

Interregional milk movements

Total interregional shipments of milk were substantially less than intermarket shipments and did not vary greatly among the models (Table 3). The total was a little less than one billion pounds for the five regions considered. The exports were from the North Central region.

Plant-size restrictions can affect the comparative advantage of processing firms in the various regions. For example, Model A indicates that the North Central region has a comparative advantage in generating economies of size in processing because of its location relative to production supplies, the demand of its large population base, and potential export markets. With an estimated plant size of 112 million pounds per month, there was an economic advantage and transhipments of the final product were indicated. About one-third of the exports from the region were as processed milk. With the plant-size environment made more

Table 3. Net regional monthly imports and exports of raw and processed Grade A fluid milk, Models A, B, and C

	Processed milk			Total milk		
	Model			Model		
	A	B	C	A	B	C
	million pounds					
	Net imports					
Net importing regions						
Western	0.0	0.3	0.0	44.2	373.3	60.2
West South Central	10.8	20.4	3.0	127.4	28.7	135.8
Southern	180.4	80.0	10.9	292.7	411.3	404.6
Northeast	122.2	26.1	27.1	457.6	139.3	321.3
	Net exports					
Net exporting region						
North Central	313.4	126.8	41.0	921.9	952.6	921.9

restrictive, the plants in the North Central region were unable to attain such economies. As a result, interregional shipments of raw milk increased and additional processing occurred in the more distant regions such as the West and South.

Net imports by regions indicated substantially larger interregional shipments for the West under Model B than under Models A or C. The differences reflect to some extent differences in the assumptions regarding relative prices as discussed earlier. Consequently, net imports for the Western area, and the corollary of unused production, may be overestimated in Model B. In the Northeast actual prices were somewhat higher than prices under the base-point pricing system, and the indicated net imports under Model B may be understated.

Conclusions
